1. Introduction

Photochemistry comprises the chemical reactions of atoms or molecules that have been electronically excited by absorption of light with wavelength in the range of 200 nm to ca. 700 nm. In thermal reactions heat is transferred to the respective ground state species, generating a Maxwell – Boltzmann energy distribution. In contrast, photochemical excitation proceeds via the absorption of discrete quanta of energy. The advantages of photochemistry, in particular concerning one-quantum or quasi-stoichiometric photochemistry, can be summarized as follows:

1) Light may be considered as a highly specific and ecologically clean "reagent"
2) Photochemical methods offer less "aggressive" routes in chemical synthesis than thermal ones
3) Photochemical reactions may contribute to the safety of industrial processes, because they are generally performed at, or below, room temperature
4) Photochemically reacting organic compounds do not require any protecting groups
5) Many conventional syntheses can be shortened by inserting photochemical reaction steps

About 8000 preparative organic photoreactions, classified in ca. 550 reaction types, are known [1] which may be economically feasible if they lead in one step to products of unusual structure, hereby shortening conventional syntheses considerably [2]. In contrast to this fact, industrial photochemistry has been ill-famed for many decades, and successful processes and production units are kept out of publicity because the developed know-how is of considerable value. Thus, it is quite difficult to collect and review data on photochemical technology and to discuss the evolution in this field. Nevertheless, in this article, the problems which always accompany the scaleup of photoreactions are treated as well as the relevant basic photochemical knowledge.

2. Primary Photophysical Processes

The energy E (in joules) of a single photon is given by the Planck equation

$$E = h\nu = \frac{hc}{\lambda} \quad (1)$$

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a19_573

where h is Planck's constant (6.6265×10^{-34} J s), ν the frequency of radiation (s^{-1}), c the velocity of light (2.9979×10^{8} m/s), and λ the wavelength (m). One mole of photons is also defined as one einstein. Usually the energies transferred in photochemical reactions exceed the typical activation energies of thermal reactions and also the dissociation energies of chemical bonds (Table 1).

When a system is irradiated, the light may be transmitted, scattered, refracted, or absorbed. The first law of photochemistry, formulated by Grotthus (1817) and Draper (1843), states that only light which is absorbed by a molecule is effective in producing a reaction which changes the molecule. This implies that there must be some overlap between the range of wavelengths of the light entering the system and those absorbed by the starting material. Therefore, the absorption spectrum of the latter and the spectral energy distribution of the light source should be known. It is also advantageous to know the wavelength-dependent transparency of the wall in front of the light source and the absorption spectra of the solvents and photoproducts.

The probability of absorbing a photon depends on the capability of the incident radiation to transform the electronic distribution of the molecule's ground state into that necessary for the excited state. According to the Beer–Lambert law, the absorbance A of a beam of collimated monochromatic radiation in a homogeneous isotropic medium is proportional to the absorption path length l (cm) and to the concentration c (mol/L), or–in the gas phase–to the partial pressure of the absorbing species. The law can be expressed as

$$A = \log(P_o/P) = \varepsilon c l \text{ or } P = P_o 10^{-\varepsilon c l} \tag{2}$$

where P_o is the incident radiant power, and P the power of the penetrating light; the proportionality constant ε ($L\,mol^{-1}\,cm^{-1}$) is called the molar decadic absorption coefficient.

The spectral radiant power P_{abs} (W/nm) [3] of a collimated beam absorbed along the path length l is given by the difference of the incident and penetrating radiant power:

$$P_{abs} = P_o - P \text{ or } P_{abs} = P_o\left(1 - 10^{-\varepsilon c l}\right) \tag{3}$$

Frequently, the incident radiant power P_o cannot be measured exactly. In many cases it is, however, sufficient to express P_o as 100 %, replacing Equation (3) by

$$P'_{abs} = 100\left(1 - 10^{-\varepsilon c l}\right)\% \tag{3a}$$

Furthermore, in industry it is common practice to characterize a light-absorbing substance with unknown molecular mass M_r by the absorbance $A^{1\,\%}_{1\,cm}$ of a 1 wt % solution with a 1 cm path-length. This term is related to ε by the equation

$$A^{1}_{1} = \frac{\varepsilon 10}{M_r} \tag{4}$$

When more than one light-absorbing component is present at the beginning of a photoreaction or developed in its course, the concentration c_i of any light-absorbing component i present must be considered as well as its molar decadic absorption coefficient ε_i. In this case Equation (2) must be expanded to [4]:

$$P_{abs,i} = P_o \frac{\varepsilon_i c_i \left(1 - 10^{-l \sum_{n=1}^{n} \varepsilon_n c_n}\right)}{\sum_{n=1}^{m} \varepsilon_n c_n} \tag{5}$$

The exponential term becomes negligible when $10^{-l \sum_{n=1}^{m} \varepsilon_n c_n} << 1$, to give

$$P_{abs,i} = P_o \frac{\varepsilon_i c_i}{\sum_{n=1}^{m} \varepsilon_n c_n} \tag{5a}$$

which can be simplified further by again expressing P_o as 100 %.

If the radiant power P is of the order of magnitude which is common in conventional photochemical systems, the concentration of electronically excited molecules is very low and the probability that an excited molecule absorbs a second photon is also low. In laser photochemistry, however, the concentration of excited molecules may increase to an extent which renders biphotonic processes possible.

A universal integral quantum yield φ defines the number of events which occur per photon absorbed by the system [3]

$$\varphi = \frac{\text{number of events}}{\text{number of photons absorbed}} \tag{6}$$

In this generalized form, φ can be used to describe photoexcitation and physical deactivation processes of a typical organic molecule, as

Table 1. Photon energies at different wavelengths compared with dissociation energies of selected single bonds

Wavelength, nm	Energy, kJ/einstein	Single bond	Dissociation energy, kJ/mol
200	598.2	HO – H	498
250	478.6	H – Cl	432
300	398.8	H – Br	366
350	341.8	Ph – Br	332
400	299.1	H – I	299
450	265.9	Cl – Cl	240
500	239.3	Me – I	235
550	217.5	HO – OH	213
600	199.4	Br – Br	193
650	184.1	$Me_2N - NMe_2$	180
700	170.9	I – I	151

shown in Figure 1. These physical deactivation processes are summarized in the second law of photochemistry

$$\varphi_{IC} + \varphi_{ISC(S)} + \varphi_{ISC(T)} + \varphi_F + \varphi_P = 1 \quad (7)$$

Figure 1. Modified Jablonski diagram for a typical organic molecule. Vibrational levels are omitted for clearness.
The transitions a to f are defined as follows (the lifetime in s is given in parentheses):
a) Excitation $S_o + h\nu \rightarrow S_1$ (10^{-15}); b) Internal conversion (IC) $S_1 \rightarrow S_o + \Delta$ ($10^{-9} - 10^{-7}$); c) Fluorescent emission (F) $S_1 \rightarrow S_o + h\nu_F$ ($10^{-11} - 10^{-6}$); d) Intersystem crossing [ISC(S)] $S_1 \rightarrow T_1 + \Delta$ ($10^{-11} - 10^{-8}$); e) Phosphorescent emission (P) $T_1 \rightarrow S_o + h\nu_P$ ($10^{-3} - 10^{+2}$); f) Intersystem crossing [ISC(T)] $T_1 \rightarrow S_o + \Delta$ ($10^{-3} - 10^{+2}$)

At room temperature excitation starts from the lowest vibrational level of the S_o state leading to vibrational sublevels of the S_1 state. Electron spins, characterized by arrows in boxes in Figure 1, are antiparallel to its "partner" in singlet states S and parallel in triplet states T. According to Hund's rule, triplet excited states are lower in energy than the corresponding singlet excited states. Therefore, after very rapid vibrational equilibration to the zeroth vibrational level of the excited states, the electronically excited molecule can partly redistribute its energy by radiationless intersystem crossing [ISC(S)] to a lower lying triplet state T_1. In most organic molecules the only strong absorptions and emissions are singlet – singlet in character, the transitions

$$S_o \underset{-h\nu}{\overset{h\nu}{\rightleftharpoons}} T_1 \quad (8)$$

are prohibited [5]. T_1 therefore has a much longer lifetime than S_1 (Fig. 1), hence the probability that photochemical reactions (including sensitized ones) occur from T_1 is much higher. Photosensitized reactions are those in which light is not absorbed by the substrate which undergoes the chemical reaction, but by an added sensitizer. The sensitizer undergoes no chemical change, but merely transfers electronic energy to the substrate or undergoes a reversible redox process with the substrate.

According to the Wigner spin conservation rule the energy of an electronically excited molecule can only be transferred to a ground-state molecule by the following processes:
Singlet energy transfer

$$^aS_1\,(\uparrow\downarrow)* + {}^bS_o\,(\uparrow\downarrow) \longrightarrow {}^aS_o\,(\uparrow\downarrow) + {}^bS_1\,(\uparrow\downarrow)* \quad (9)$$

Triplet energy transfer

$$^aT_1\,(\uparrow\uparrow)* + {}^bS_o\,(\uparrow\downarrow) \longrightarrow {}^aS_o\,(\uparrow\downarrow) + {}^bT_1\,(\uparrow\uparrow)* \quad (10)$$

where a and b denote different molecules. A third form of energy transfer is electron transfer,

a true photochemical reaction which can occur from the singlet as well as from the triplet state

$$D_1 + A_o \longrightarrow (D^{\cdot +} A^{\cdot -}) \quad (11)$$
$$D_3 + A_o \longrightarrow (D^{\cdot +} A^{\cdot -}) \quad (12)$$

D_1 and D_3 are donors and A_o is the acceptor.

To complete the description of primary photophysical processes, two types of electron transitions which are related to basic chemical structures can be distinguished (Fig. 2). In unsaturated compounds with carbon – carbon multiple bonds, light absorption produces $\pi \rightarrow \pi*$ transitions, whereas excitation of compounds containing heteroatoms such as N,O,S in general produce $n \rightarrow \pi*$ transitions. The electronic transition $(\pi, \pi*)$ may be described approximately as the promotion of an electron from a "bonding" π orbital to an "antibonding" π orbital, designated $\pi*$. In contrast, the $n \rightarrow \pi*$ transition is an electronic transition described approximately as the promotion of an electron from a "nonbonding" (lone pair) n orbital to an "antibonding" π orbital, also designated $\pi*$.

Figure 2. Absorption regions associated with the different types of electron transitions

These light-induced electron transitions exhibit different properties. The first $(\pi, \pi*)$ absorption band of aromatic hydrocarbons is more intense than the $(n, \pi*)$ transitions of aromatic carbonyl compounds. The $(n, \pi*)$ states generally have longer lifetimes than $(\pi, \pi*)$ states. The energy differences $\Delta E\,(S_1 - T_1)$ between the lowest excited $(\pi, \pi*)$ singlet and triplet states are much larger than those of the $(n, \pi*)$ states, e.g., in carbonyl systems. The variation in molecular geometry of the various excited states derived from $(\pi, \pi*)$ and $(n, \pi*)$ transitions determine their photochemical behavior.

Ketones are often used as sensitizers because their lowest excited singlet and triplet states are favorably situated between the singlet and the triplet state of many acceptors. However, the triplet state of ketones may bring about different processes, e.g., radical reactions started by hydrogen abstraction. Sensitization has advantages over direct irradiation because it enables irradiation at convenient wavelengths; several simple chromophores absorb at very short wavelengths at which mercury lamps, which are commonly used, are ineffective. Sensitizers in contrast absorb at the wavelengths emitted by mercury lamps.

Figure 3. Thickness of the reaction zone l' (90 % absorption) as a function of the concentration c for different values of ε_λ

3. Performance of Photochemical Reactions

3.1. Photoreactor Design

According to the Beer – Lambert law photoreactions are characterized by their spatial inhomogeneity. For a reaction zone l' defined by an absorbance $A = 1$ (90 % light absorption) the term $1/\varepsilon c$ (cm) determines its thickness (Fig. 3). High molar absorption coefficients ε (L mol^{-1} cm^{-1})

Figure 4. Fundamental arrangements of the most important photoreactor types [6] (reproduced with permission)
For description of A, B, and C see text

and/or high substrate concentrations c (mol/L) may reduce the thickness of l' to several micrometers, i.e., to a region where even the turbulent flow of a liquid becomes laminar due to adhesive forces from the wall. This results in a decreasing contribution of macroscopic homogenization processes to the exchange of reactants out of and into the reaction zone. It is therefore not always favorable to use light which corresponds to the substrate's absorption maximum. Irradiation of less absorbing parts of the chosen absorption band may extend the reaction zone l' significantly [6].

In industrial photochemistry, high substrate concentrations are preferred because of the cost of solvent losses and recycling. The disadvantages that arise from small reaction zones l' must be compensated for by an adequate photoreactor design. There are three technically suitable types of reactor which are outlined in Figure 4. In Figure 4A the photoreaction zone l' is located in the solid – liquid contact region where $1/\varepsilon\, c << 1$ cm, the zone l' can only be removed from the wall by a flow rate of twice the velocity of sound. To overcome this difficulty, in this case different methods may be applied, e.g., using the turbulent flow of the irradiated liquid by tangential injection into the reactor (Fig. 5) [7]. Another very effective approach is the gas-bubble photoreactor Fig. 6) [8]. Here, the solution flows fast in upward direction and entrains many small gas bubbles. These bubbles avoid filming and/or destructive overirradiation by producing local turbulences while passing the solution along the light permeable reactor wall (Fig. 6). This system is also useful for the photosensitized production of singlet oxygen (see Section 6.2) and for photochlorinations (see Section 4.1). It also has to be considered that solvent vapor taken along with the gas has to be condensed when leaving the photoreactor. In Figure 4B the reaction zone l' is located in the liquid – liquid contact region, provided that both liquids flowing downwards are nonmiscible and that the photoreactive light penetrates the liquid in front of the light source, whereas the light-absorbing substrate should only be soluble in the liquid that is more remote from the light source [9]. In this reactor type the two liquids must flow downwards. The proportions of the following parameters must be defined:

1) Density and viscosity of both liquids
2) Slit width which limits the space available for the two nonmiscible liquids flowing between the two concentric tubes which surround the tube-like lamp
3) The flow rates of both liquids
4) The pressure gradient

The literature only deals with one liquid flowing between two concentric tubes [10]. The flow of two nonmiscible liquids can also be treated mathematically, assuming that the concentric tubes are infinite in length and that the flow is

laminar. In this case combined differential equations can be formed, taking into account the gravitational, frictional, and compressive forces of the two liquids. The relevant limiting conditions are that the flow rate on the walls is zero, and that the flow rate and shear stress in the separation layer between the two liquids are of the same magnitude. The resulting system of differential equations can then be resolved by iteration methods using a computer.

Figure 5. Example of a type 4A photoreactor: Free hanging UV source inside an open quartz glass tube; stainless steel jacket; injection of the liquid to produce a tangential flow; removable front plate. (VitaTec UV-Systeme GmbH) [7]

Figure 6. Example of a modified type A photoreactor: The QVF – Pfoertner photoreactor, creating local turbulences by small gas bubbles in the upwardly fast flowing solution [8] (QVF Glastechnik GmbH)

The structural features of the reactor shown in Figure 7 allow circulation of the liquids by pumping just the heavier phase. The less dense liquid automatically rises in the tubes outside the reactor and is forced to move down inside the reactor by friction with the falling heavier phase. It is possible to vary the motion of the

contact layer, i.e., of the photoreaction zone l', by altering the flow rate within limits [9].

Figure 7. Example for a complete irradiation system containing a photoreactor of type 4 B
a) Partition wall; b) Outlet; c) Inlet; d) Heat exchanger inlet; e) Heat exchanger outlet

In Figure 4C the reaction zone l' is located in the gas – liquid contact zone, i.e., the surface of a falling film containing the substrate is irradiated. This can be realized with a variety of reactor types. One example is given in Figure 8, where the falling film is formed at the top of the reactor. Any splashes occurring on the lamp's housing are washed with the same solvent used in the irradiated solution which is thus continuously diluted [11]. Figure 9 shows a very special type of photoreactor. In this UV autoclave, photoreactions can be performed under pressures up to 15 MPa; mixing of the irradiated system is achieved by a magnetic stirrer [12]. Problems connected with photoreactor design have been intensively studied by J. C. André and coworkers [13].

Figure 8. Example for a falling film photoreactor of type 4 C [11]
a) Formation of the falling film; b) Light source; c) Falling film; d) Cooling; e) Solvent for cleaning the lamp housing

3.2. Light Sources

In photochemistry two fundamental arrangements of light sources exist. In one the lamp, a long cylinder, is surrounded by a cooling jacket that is immersed in the reaction solution (Fig. 10); in the other, the reaction mixture is irradiated from outside using a focussing reflector. The energy output of a lamp can best be utilized by performing the photochemical reaction within the space between two concentric tubes surrounding the lamp, or by applying the aforementioned immersion mode. The choice of light source is dictated by a suitable combination of spectral energy distribution, radiant power, and

Figure 9. Example of an UV autoclave [12]
a) Housing for magnetic stirrer; b) 15 MPa resistant steel tube with attachment; c) Light source

filter for the special case considered. If the reactant absorbs in more than one region of the spectrum, as nearly all organic molecules do, irradiation in different bands may induce different photochemical reactions. Thus, irradiation is mainly restricted to absorption in the longest wavelength region by applying the usual polychromatic lamps in combination with a suitable cutoff filter. For a typical medium pressure mercury lamp with an electrical power input of 10 – 60 kW, the total output of photochemically utilizable light (200 – 600 nm) averages 44.2 %. The insertion of boron silicate glass decreases the light output (300 – 600 nm) to 19.6 %.

Furthermore, is it noteworthy that the light output of mercury medium-pressure lamps (Figure 10) at $\lambda = 200 - 600$ nm, expressed as percentage of the electrical power input, increases more than proportional relative to the latter, as can be recognized from the following comparison (Table 2) [2].

Table 2. Percentage of light output relative to the electrical power input

Electrical power input, kW	Light output (220 – 600 nm), %
2	19.5
4	27.4
10	46.3
20	43.5

Reason for this effect is the formation of ″van der Waals″ collision complexes consisting of two mercury atoms. Starting with 2 kW their number increases with increasing electrical power input and remains nearly constant from 10 – 60 kW [2]. The light emitted by these collision complexes adds to the light output of excited single mercury atoms which are the original emitting species of mercury lamps.

For technical purposes it is useful to know the conversion of the radiant power P in watts emitted by the lamp into the photon flow φ_{P} in einstein per hour as a function of the wavelength λ in nanometers:

$$\varphi_{\mathrm{P}} = 3.01 \times 10^{-5} \lambda P \tag{13}$$

The majority of light sources are of the immersion lamp type (see Fig. 10). The spectral energy distributions of the widely used medium-pressure mercury lamps with a power input of 2 – 60 kW are given in Table 3. Medium-pressure mercury lamps can be doped with other metals resulting in a weakening of their original polychromatic light in favor of new emission lines which are characteristic of the added metal. Antimony offers light in the range 270 – 300 nm where undoped mercury lamps emit poorly. TlI and GaI create very strong lines at 535 nm and 417 nm, respectively.

Newly developed incoherent excimer sources are now available for performing photochemical reactions (Fig. 11) [14]. Because excimer sources do not possess a stable ground state, self-absorption cannot occur. This should lead to an intrinsic efficiency of at least 30 %. But

Figure 10. Fundamental arrangement of a mercury medium-pressure lamp with an electrical input 2 – 60 kW, equipped with cooling jacket and gasket.

the surrounding metal net which is necessary for the dielectric-barrier discharge lowers the efficiency to ca. 10 % by absorption and reflection of the generated light. The excimer light sources are operated with frequencies of about 50 kHz, and voltage amplitudes of 5 – 10 kV are required to ignite the discharge. Under those conditions, bursts of light pulses with a repetition frequency of about 100 kHz are produced. Compared with mercury or xenon lamps excimer sources generate considerable less heat. As immersion lamps they are delivered with an already installed cooling system which makes further cooling of the irradiated solution unnecessary. With proper choice of the gas mixture, excimers can be found that radiate only in a narrow specified wavelengths range, e.g., at 172, 222, and 308 nm. Disadvantage for an upscaling of photoreactions performed with excimer sources is the limitation of their electrical power input to 1.5 kW. The most striking difference to other UV sources, however, is the wide choice of geometries. The possibility of constructing large flat radiating panels as well as hollow cyclinders filled with UV radiation could lead to a variety of new photochemical applications [14].

In addition to artificial light sources, concentrated sunlight has been taken into consideration for the photochemical production of fine chemicals [15]. Here, the photoreaction occurs in a solution flowing through a glass tube in the focal line of a parabolic trough with suitable light

reflecting properties. The sun tracking is performed automatically three-dimensional on two axes, e.g., with a Helioman Module from MAN (Fig. 12) [16]. Irradiation with sunlight initiates not only photoreactions but also heats up the solution. This limits the concentration of sunlight by parabolic mirrors, even when the solution is rapidly flowing through external heat exchangers. In the Helioman Module (Fig. 12) some reflecting parts are deleted, in order to show how they are arranged. The Helioman Module is part of the so-called PROPHIS system [17] and the relevant data are given in Table 4.

Table 4. Data for the Helioman Module

are preferred because traces of polyvalent metal ions, e.g., from stainless steel, may change the direction of a photoreaction considerably. Titanium vessels are required only if there is contact with extremely corrosive solutions which occur in photonitrosation processes. Pumps are another source of possible contamination. Therefore, centrifugal pumps with magnetic coupling are recommended, provided that all parts in con-

tact with the pumped medium consist of materials with suitable properties.

Figure 11. Excimer immersion lamp [14] (Heraeus Noblelight)

Also important is the elimination of UV attenuating films which may result from photoreactions and/or from algae in the cooling water and which are frequently invisible. These films are best removed with an aqueous solution of 10 % HF. In addition, the appearance of hazardous electrostatic charges is observed when 1,4-dioxane or other ethers, and tetrachloromethane circulate as solvents through tubes made of glass or polyfluorinated plastics. Electrostatic charging can be avoided not by earthing the apparatus but by using an admixture of protic solvents, e.g., 2 vol % *tert*-butanol, which do not participate in the photoreaction.

3.4. Scaleup

Photoreactions can either be batch or continuously operated. The typical *batch reactor* for photoreactions in a homogeneous liquid phase consists of a large vessel containing an appropriate number of lamps and a stirring device, and can be maintained under inert gas if necessary (Fig. 13). A great part of the electrical power supplied to the lamp is transferred into heat; the proportion decreases from 63 % for a 20 kW lamp to 37 % for a 60 kW lamp. This heat is usually removed by water flowing between the inner and outer wall (quartz or glass) surrounding the lamp. The cooling water may be replaced by a filter solution flowing through an external heat exchanger. If the filter solution does not come into contact with metals it is advantageous to replace the cooling water by an aqueous solution of 35 g/L $CuSO_4 \cdot 5\,H_2O$ (optical path length 1 cm, cutoff at 300 nm). In this way, convection heat as well as radiant heat is removed, because in addition to the UV light of 200 – 300 nm, the Cu^{2+} ion absorbs strongly in the infrared region.

An apparatus using an immersion lamp to perform gas – liquid reactions such as photonitrosation is shown in Figure 14.

Continuously working photoreactors are mainly used for light-induced chain reactions in vapor-, liquid-, or mixed-phase reactions. Because of the very high reaction rates only short contact times are necessary. These can be best achieved in a flow system, e.g., in concentric tubes surrounding the lamp [18].

Scaleup Problems. Though theoretical studies concerning practical photochemistry given in [13] contribute to the understanding of the problems involved, the best approach to scaleup

Figure 12. Arrangement for the photochemical application of sunlight (MAN Helioman Module [16])
1, 5, 11, 12, 13 = System of tubes for transportation of the irradiated liquid; 2 = Solar sensor; 3 = Light absorbing tube; 4 = Reflector, 8, 9, 10 = Reflector support

a photoreaction seems to be the enlarging of a laboratory-type prototype reactor with the important parameters being changed as little as possible. For the same reason initial pilot-plant studies should be carried out using a reactor with only one production-size lamp. Once the characteristics of a flow reactor with one lamp are understood, further scaleup is simply a matter of adding more lamps and/or more reactors.

3.5. Economic Considerations

With respect to light-induced chemical transformations, the universal quantum yield φ (see Eq. 6) must be replaced by the quantum yield φ':

$$\varphi' = \frac{\text{moles of product obtained}}{\text{einsteins of light absorbed}} \tag{14}$$

which is also measured in terms of monochromatic light by complicated actinometric systems. In industrial photochemistry this method is not useful for determining the product-specific electrical cost of running a light source. In most cases the starting material absorbs more than one of the lamp's emission lines. Therefore, to consider the absorption of an entire spectral region rather than one wavelength a quantum yield φ'' must be defined which can be determined by simple measurement of the moles of product obtained per kW · h of electrical energy consumed by the lamp. Such an estimation should include all utilizable radiation filling up the whole solid angle. This is the case when an immersion lamp is used.

$$\varphi'' = \frac{\text{moles product / kW·h}}{\text{einsteins / kW·h}} \tag{15}$$

Assuming that about 10 % of the energy input is utilized as photochemically active light, most of the total energy input has to be removed as heat. This increases the electrical cost and must be taken into account by multiplying the energy input of the lamp by a factor of about 3. In addition to the cost of equipment and the cost arising from the limited lifetimes of the lamps (i.e., 2000 – 6000 h for Hg low pressure lamps and 1000 – 3000 h for Hg medium pressure lamps), it must be considered that a radiant power of 1 einstein/h is equivalent to 130.8 W at 254 nm but only to 60.8 W at 546 nm (both are Hg emission lines).

Figure 14. Photoreactor for gas-liquid reactions
a) Cooling; b) Light source

The costs resulting from solvent losses and recycling may exceed the electrical cost of running the lamp. For the complete photochemical conversion of a compound dissolved in ether with a concentration of 1 wt % into the desired product, ca. 100 t of solvent need to be recycled to obtain 1 t of product. This requires 1.054 $\times 10^4$ kW · h (calculated from the specific heat of ether C_p (25 °C) = 172.5 $\times 10^{-3}$ J/mol and from its heat of vaporization = 26.508 $\times 10^3$ J/mol).

Many chemists who are not specialized in photochemistry are not aware of the fact that especially in quasi-stoichiometric photoreactions the molecular mass of the photoproduct must be taken into account, as it determines the amount of material in kg or tons produced by photoreactions with the same molar conversion in the same irradiation time (Fig. 15) [2].

Figure 15. Molecular mass and yield of the photoproduct using a 20 kW Hg medium pressure lamp radiating 12.7 einstein/h at 366 nm at various molar conversions (φ'). Reproduced with permission [6]

A theoretical treatment of the determination of the most suitable irradiation conditions can be found in [13]. One way to characterize a photoreaction is to consider its quantum yield φ'. Light-induced chain reactions are indicated by $\varphi' > 1$, whereas in photochemical conversions with $\varphi' \leq 1$ light plays the role of a reagent. Therefore, such photoreactions may be considered as "quasi-stoichiometric". Examples of both types of photoreactions are given in Chapters 4 and 5.

4. Light-Induced Chain Reactions

4.1. Photohalogenation

The values of λ_{max} and ε_{max} of the halogens X_2 increase with increasing atomic number (Table 6). The small value of ε_{max} reflects the forbidden character of the transition which becomes progressively more allowed as one moves to heavier atoms. The transition responsible for these absorption bands is presumed to be a singlet – triplet promotion which largely results in the formation of halogen atoms [5]:

Table 6. Characteristic light absorption data of the halogen molecules in the gas phase

Halogen X_2	λ_{max}, nm	ε_{max}, L mol^{-1}cm^{-1}
F_2	284.5	6
Cl_2	330	66
Br_2	420	200
I_2	520	950

$$X_2(\uparrow\downarrow) \xrightarrow{h\nu} X_2(\uparrow\uparrow)^* \longrightarrow 2X\cdot \quad (16)$$

The greater the dissociation energy of X_2 (Table 1), the greater is the reactivity of the radicals formed by dissociation; in contrast, cleavage of weak bonds leads to less reactive radicals. Thus, light-induced chain reactions may occur when Cl_2 or Br_2 are involved, but not with I_2.

Photochlorinations. Industrial photochlorinations are determined by the quantum yields, which depend on the structure of the hydrocarbon to be photochlorinated and are in the range $10^3 - 10^6$. Even traces of oxygen act as an inhibitor. The reaction chains may be interrupted by removal of either a chlorine atom or a hydrocarbon radical:

$$Cl\cdot + O_2 \rightarrow ClO_2 \quad (17)$$
$$R\cdot + O_2 \rightarrow RO\cdot_2 \quad (18)$$

The ClO_2 molecules and $RO_2\cdot$ radicals enter into secondary reactions which mainly result in the formation of stable molecules without regeneration of chain-propagating free radicals.

Since the probability of chain termination increases with the concentration of newly formed chain-starting radicals, the economy of photochlorination decreases with increasing photon irradiance E_P (einstein m^{-2} s^{-1}). Here, the use of weak lamps is preferred. Additionally, the speed of photochlorination, e.g., of toluene, depends on the chlorine excitation wavelength. The best conditions are given when the maximum light emission of the lamp lies in the blue region where the reaction zone l' (cm) becomes larger. This is due to the variation of the molar absorption coefficient ε of chlorine. Thus, at 350 nm 99 % of the light is absorbed within a very short distance leading to high local concentrations of chlorine atoms which favor recombination and thereby reduce the chain reactions (see Section 3.1).

Photochlorination can occur according to two different mechanisms:

1) Addition of chlorine
2) Substitution by chlorine

Addition of Chlorine. The synthesis of the pesticide *lindane* (γ-hexachlorocyclohexane) is a well-known example of photochemical additions of chlorine to benzene. Because of its toxicity, lindane is no more commonly used and the production of lindane will not be discussed here. More important is the industrial preparation of oxalyl chloride which is a reagent with many applications in the production of pharmaceuticals, agrochemicals, etc. Since syntheses of oxalyl chloride starting from oxalic acid have many disadvantages, such as low yields, high amounts of waste, purification and safety problems, Tessenderlo Chemie in Belgium has developed a suitable photochemical procedure by improving the method of producing oxalyl chloride from ethylene carbonate, already known since 1936. This procedure combines the photochemical addition of chlorine with photochlorination by substitution, yielding the corresponding tetrachloro compound which can be decomposed into oxalyl chloride and phosgene (see Eq. 19).

Photochlorination by Substitution. Photochlorination by substitution proceeds via the following mechanism:
Initiation: see Equation (16)
Propagation:

$$RH + Cl\cdot \longrightarrow R\cdot + HCl \quad (20)$$
$$R\cdot + Cl_2 \longrightarrow RCl + Cl\cdot \quad (21)$$

Termination:

$$R\cdot + R\cdot \longrightarrow R_2 \quad (22)$$
$$R\cdot + Cl\cdot \longrightarrow RCl \quad (23)$$
$$Cl\cdot + Cl\cdot \longrightarrow Cl_2 \quad (24)$$

An important example of the substitution mechanism is the *production of benzyl chloride*

by photochlorination of toluene. Here, the heat from the uncooled lamps together with the heat of reaction maintain the toluene under reflux. Thus, photochlorination of the aromatic ring can be avoided. Photochlorination of the aromatic ring is also catalyzed by metallic impurities in the toluene; this effect can be inhibited by adding complexing agents because purification of the toluene by distillation prior to side-chain photochlorination is economically not feasible. The ratio $Ar-CH_2Cl$: $Ar-CHCl_2$: $Ar-CCl_3$ is 10 : 1 : 0.1.

The chain reaction during substitution of hydrogen atoms by chlorine proceeds because the energy of 432 kJ/mol obtained through the formation of each mol HCl exceeds the dissociation energy of Cl_2 (see Table 1). This concerns also the side-chain photochlorination of *p*-xylene to $\alpha,\alpha,\alpha,\alpha',\alpha',\alpha'$-hexachloro-*p*-xylene (Eq. 25).

(25)

This is the first step in the aramid fiber production (→ High-Performance Fibers, Chap. 3.2.1.) at Aramid Products V.o.F./Netherlands, a subsidiary of Akzo Nobel N.V. The semi-batch reaction is performed in two photoreactors, each of them equipped with three UV lamps of 10 kW. Similar to the production of benzylchloride the reaction temperature is 80 – 140 °C, in order to avoid addition of chlorine to the benzene ring. At the end of the reaction the concentration of hexachloro-*p*-xylene is 98.5 % without purification. In the presence of a catalyst hexachloro-*p*-xylene reacts with terephthalic acid to terephthalyl chloride which is polymerized with *p*-phenylene diamine to give poly-*p*-phenylene-terephthalylamide (PPTA) with a capacity of ca. 10 000 t/a.

Part of the polymer PPTA is then spun to Twaron, a fiber with high thermal and chemical resistance whose tensile strength is five times higher than that of steel of the same weight.

Phosgene is a highly toxic gas which has been used in the chemical industry in enormous quantities for chloroformylations, carbonylations, formation of isonitriles, etc. Because of its toxic character substitutes for phosgene are used whenever possible. The liquid trichloromethyl chloroformate behaves like 2 mol phosgene in chemical reactions and is therefore called "diphosgene". Its use is safer and easier than that of phosgene. Even safer, especially during transport and storage, is the crystalline bis(trichloromethyl)carbonate or "triphosgene" (→ Phosgene, Chap. 2.2.; → Isocyanates, Organic, Chap. 4.).

In a suitable medium (e.g., dissolved in toluene) it reacts like 3 mol phosgene. During the photochlorination of methyl chloroformate, or dimethylcarbonate, the hydrogen atoms of the methyl groups are stepwise substituted by chlorine atoms. (Eqs. 26 and 27). Both reactions are exothermic and their $-\Delta H$ exceeds the dissociation energy of Cl_2, hereby initiating chain reactions which guarantee relatively short irradiation times, even with sunlight

+ 3 HCl – 382 kJ (26)

+ 6 HCl – 763 kJ (27)

Photobromination. The photobromination of toluene proceeds according the following reactions:

$$Br_2 + h\nu \longrightarrow Br_2* \quad (28)$$

$$Br_2* \longrightarrow Br\cdot + Br\cdot \quad (29)$$

$$Br\cdot + Br\cdot \longrightarrow Br_2 \quad (30)$$

$$PhCH_3 + Br_2 \longrightarrow PhCH\cdot_2 + HBr \quad (31)$$

$$\Delta H = -10\,\text{kJ/mol}$$

$$\text{PhCH}\cdot_2 + \text{Br}_2 \longrightarrow \text{PhCH}_2\text{Br} + \text{Br}\cdot \tag{32}$$

$$\Delta H = -21\,\text{kJ/mol}$$

The chain reactions (31) and (32) are exothermic processes. The heats of formation and dissociation involved in the photobromination of toluene are as follows:
Heats of dissociation

$$\Delta H\,(\text{Br}-\text{Br}) = 193\,\text{kJ/mol}$$
$$\Delta H\,(\text{PhCH}_2-\text{H}) = 356\,\text{kJ/mol}$$

Heats of formation

$$\Delta H\,(\text{H}-\text{Br}) = -366\,\text{kJ/mol}$$
$$\Delta H\,(\text{PhCH}_2-\text{Br}) = -214\,\text{kJ/mol}$$

The dissociation energy of the Br_2 molecule (193 kJ/mol) corresponds to a wavelength of 620 nm. Although Br_2 absorbs efficiently at 511 nm, irradiation with light of shorter wavelengths is necessary to start the chain reaction:

λ, nm	Absorption	Photolysis
620	scarce	no
550	efficient	no
511	efficient	yes

4.2. Photosulfochlorination

Sulfochlorination of *n*-alkanes produces almost random substitution and starts, like photochlorination, with the formation of chlorine atoms (Eq. 16) and the formation of alkyl radicals R· (Eq. 20). The propagation is then supplemented by

$$\text{R}\cdot + \text{SO}_2 \longrightarrow \text{RSO}_2\cdot \tag{33}$$
$$\text{RSO}_2\cdot + \text{Cl}_2 \longrightarrow \text{RSO}_2\text{Cl} + \text{Cl}\cdot \tag{34}$$

and the termination by

$$\text{RSO}_2\cdot + \text{Cl}\cdot \longrightarrow \text{RSO}_2\text{Cl} \tag{35}$$

Analogous to photochlorinations, oxygen is also a powerful inhibitor for sulfochlorinations. The alkylsulfonyl chlorides are starting materials for the preparation of detergents, emulsifiers, corrosion inhibitors, and auxiliaries for the textile and paper industries.

4.3. Photosulfoxidation

The $(n, \pi*)$ excitation of SO_2 dissolved in hydrocarbons exhibits an absorption maximum at 290 nm and its singlet energy lies below 380 kJ/mol. Since the dissociation energies for C – H bonds in ethyl – CH_2 and in methyl groups are given by 410 kJ/mol and 435 kJ/mol, respectively, the observed hydrogen abstraction might be considered to proceed via an $(n, \pi*)$ triplet as well as via an exciplex $(SO_2 \cdot\cdot RH)*$. Therefore, the reaction mechanism can be generalized as follows:
Initiation

$$\text{SO}_2 + h\nu \longrightarrow \text{SO}_2* \tag{36}$$

$$\text{RH} + \text{SO}_2* \longrightarrow \text{R}\cdot + \text{SO}_2\text{H} \tag{37}$$

Propagation

$$\text{R}\cdot + \text{SO}_2 \longrightarrow \text{RSO}_2\cdot \tag{38}$$

$$\text{RSO}_2\cdot + \text{O}_2 \longrightarrow \text{RSO}_2\text{OO}\cdot \tag{39}$$

$$\text{RSO}_2\text{OO}\cdot + \text{RH} \longrightarrow \text{RSO}_2\text{OOH} + \text{R}\cdot \tag{40}$$

Termination

$$\text{RSO}_2\text{OOH} + \text{H}_2\text{O} + \text{SO}_2 \longrightarrow \text{RSO}_3\text{H} + \text{H}_2\text{SO}_4 \tag{41}$$

In the absence of water the peroxysulfonic acid RSO_2OOH is cleaved into $RSO_2O\cdot$ and HO· ; both radicals are able to enter the propagation sequence:
Propagation

$$\text{RSO}_2\text{OOH} \longrightarrow \text{RSO}_2\text{O}\cdot + \text{HO}\cdot \tag{42}$$

$$\text{RSO}_2\text{O}\cdot + \text{RH} \longrightarrow \text{RSO}_2\text{OH} + \text{R}\cdot \tag{43}$$

$$\text{HO}\cdot + \text{RH} \longrightarrow \text{R}\cdot + \text{H}_2\text{O} \tag{44}$$

The radicals $RSO_2O\cdot$ and HO· may abstract hydrogen from the hydrocarbon, thereby forming alkyl radicals R·. The sulfoxidation becomes autocatalytic and irradiation is only necessary to initiate the reaction sequence.

In practice the peroxysulfonic acids are continuously *extracted with water.* This process prevents formation of polysubstituted alkanes. Further reaction with SO_2 produces the sulfonic acids shown in the termination step (Eq. 41). In this case the quantum yields obtained are very much lower than for sulfochlorination, being in the range of only $\varphi' = 7$ or 8. Nevertheless, Hoechst runs three plants operating on the light-water procedure with a total capacity of 72 000 t/a. The lamps consume 0.2 kW · h per kilogram of sulfonate produced, i.e., 5 kg/kW · h.

Such "photosulfonates" are produced and marketed, e.g., by Hoechst as detergents with good biodegradability.

4.4. Type I Photooxidation

Type I photooxidations start with hydrogen abstraction from suitable substrates, e.g., from alcohols, by photoexcited diarylketones, acetophenone, aromatic aldehydes, and their heterocyclic analogs. Further sensitizers are α-diketones such as diacetyl and benzil, camphor-1,2-diketone, and orthoquinones e.g., 9,10-phenanthrenequinone. Most substrates can only undergo Type I photooxidation with ketones or quinones with $(n, \pi*)$ excited states but not with quinoid dyes, because their $(\pi, \pi*)$ states cannot abstract H atoms.

Type I photooxidations are not very useful for industrial syntheses; on the contrary, it is important to avoid them in industrial processes by means of triplet quenchers or antioxidants, e.g., to suppress the yellowing of colorless plastics etc.

4.5. Photopolymerization

Photopolymerization by UV irradiation almost always requires the presence of a chemical photoinitiator. Depending on the type of photopolymerization, the photoinitiator system can be free-radical or ionic. Two types of free-radical photoinitiator systems exist: those that produce radicals by intermolecular hydrogen abstraction and those that produce them by intramolecular cleavage. Ionic photoinitiator systems utilize the photolysis of diazonium, sulfonium, or iodonium salts. Strong acids are thus formed which are able to initiate polymerization of electron-rich olefins, e.g., enolic ethers, or of cyclic ethers, e.g., oxiranes. Good photoinitiators are colorless and do not give rise to light-induced yellowing of the prepared polymer.

Photopolymerizations are characterized by a significant increase in the molecular mass of the starting compound. This can be achieved by linear polymerization of a monomer and/or by cross-linking. Since air-pollution problems resulting from heat-cured polymer solutions can be eliminated by photopolymerization, light-cured polymers have become more popular. In addition to further irreversible (color formation) and to reversible (photochromism) reactions, photopolymerizations also play an important role in stereolitography, resists for microlithography, and solder masks. Specially designed photocatalysts for ring-opening metathesis polymerization were developed by Ciba and applied together with unsaturated, strained cyclic monomers, oligmers, or polymers for use in imaging technique. This method also opens a wide range of new applications in microelectronics, tooling, and in the printing wiring board industry. The new photocatalysts are Ru(II) complexes and high-valent polyalkyl complexes of lower transition metals. Involved are the photochemical solvatation of Ru(II) in an aqueous 0.05 mol/L H_2SO_4 – ethanol mixture (3 : 2), e.g. (see top of next page)

and the photoinduced H_α-abstraction shown in

(47)

where L are the ligands and M is one of the above mentioned metals.

Because the world consumption of UV-curable products presents a multibillion dollar market with an annual average growth of 15 – 25 % for the coming years, radiation curing is in the midst of a profitable period which has been awaited for a long time. Development of new reactive oligomers and monomers, water-borne formulations, improved photoinitiators, and more efficient photosensitizers will presumably increase market growth.

$$Ru(NCCH_3)_6\,(Tos)_2 \xrightarrow{h\nu,\ EtOH,\ H_2O} Ru(H_2O)_6\,(Tos)_2 \qquad (45)$$

(46)

Polymerization of acrylate monomers is strongly inhibited by oxygen. Therefore, oxygen is removed from the curing environment by blanketing with inert gas.

5. Quasi-Stoichiometric Photoreactions

5.1. Photonitrosation

Photonitrosation of alkanes by light-induced cleavage of NOCl has been known since 1919. In the 1950s, Toray Industries/Japan developed the process for production of ε-caprolactam by photonitrosation of cyclohexane and installed the first production unit in 1963. This was the first process for production of nylon 6 starting from cyclohexane. Today, only 10 % of the world's ε-caprolactam capacity of ca. 2 900 000 t/a comes from photonitrosation of cyclohexane, 90 % are prepared by catalytic oxidation of cyclohexane with air. In 1975 the French company ATO Chimie used the photonitrosation of cyclododecane also for the production of nylon 12.

Nitrosyl chloride absorbs in the whole spectral range from 200 to 600 nm. Up to 500 nm the absorption spectrum consists of a continuum, whereas in the range 500 – 600 nm it is evidently structured indicating a zone of predissociation. Therefore, two mechanisms for the primary photochemical step are proposed, depending on the NOCl excitation below and above 500 nm:

NOCl excitation below 500 nm:

$$NOCl + h\nu \longrightarrow NO\cdot + Cl\cdot \qquad (48)$$

$$R^1R^2CH_2 + Cl\cdot \longrightarrow R^1R^2CH\cdot + HCl \qquad (49)$$

$$R^1R^2CH\cdot + NO\cdot \longrightarrow R^1R^2CHNO \qquad (50)$$

NOCl excitation above 500 nm:

$$NOCl + h\nu \longrightarrow NOCl* \qquad (51)$$

$$R^1R^2CH_2 + NOCl* \longrightarrow R^1R^2CH\cdot + NO\cdot + HCl \qquad (52)$$

$$R^1R^2CH\cdot + NO\cdot \longrightarrow R^1R^2CHNO \qquad (53)$$

Excess HCl is fed into the system with NOCl, transforming the photochemically obtained nitroso compound into an oxime which undergoes a Beckmann rearrangement in the presence of oleum to give ε-caprolactam and dodecyl lactam. To prevent deposition of tar on the lamps, radiation below 366 nm is removed, e.g., by adding cutoff filters to the cooling water. Continuous cleaning of the lamp housing with a falling film of concentrated H_2SO_4 is another method. Light sources are 60 kW Hg lamps doped with TlI which create a strong emission line at 535 nm. The reaction then proceeds mainly according to the second mechanism. The advantage of the second mechanism is its higher selectivity since the formation of chlorocyclohexane or chlorocyclododecane is suppressed, resulting in a higher quantum yield of the desired products. For nitrosocyclohexane the quantum yield increases from 0.7 at 350 nm to ca. 1 at 578 nm. The choice of optimal reaction conditions guarantees a cyclohexanone oxime yield > 90 %.

5.2. Photosynthesis of Previtamin D

The term previtamin D covers different types of precalciferols. Provitamin D stands for the corresponding precursors and vitamin D for the resulting calciferols. The most important components are the compounds **1a**, **1b–5a**, **5b** (see Fig. 16).

Figure 16. Important intermediates in the photosynthesis of previtamin D

The manufacturing process of vitamin D (**5a**, **5b**) involves a photochemical step in which the 9,10-bond of provitamin D (**1a**, **1b**) is cleaved by irradiation with appropriate UV light to give the (*Z*)-triene previtamin D (**2a**, **2b**). With increasing consumption of **1a**, **1b**, the photochemically formed compounds **2a**, **2b** compete with **1a**, **1b** for light absorption. Hence, **2a**, **2b** is partly photoisomerized into the (*E*)-triene tachysterol (**3a**, **3b**) and to a minor extent into the ring-closed products lumisterol (**4a**, **4b**) and provitamin D (**1a**, **1b**). The quantum yields of all these photoreactions are wavelength- dependent. Thus, the highest quantum yields are obtained for the (*Z*/*E*) isomerization of **2a**, **2b** in the region 248 – 265 nm and for the formation of lumisterol (**4a**, **4b**) above 290 nm. The conversion of **2a**, **2b** into vitamin D (**5a**, **5b**) proceeds thermally. Starting from the corresponding steroid ring B dienes, the preparation of hydroxylated vitamin D_3 metabolites such as **6** follows the same mechanism.

The D vitamins are involved in the regulation of calcium homeostatis. Vitamin deficiency leads to several diseases such as rickets which is caused by failure to deposit calcium in bones. Vitamin D_2 (ergocalciferol) is only active in mammals, whereas vitamin D_3 (cholecalciferol) is active in mammals and birds, where it also has an effect on the eggshell stability. Hence, vitamin D_3 is produced on a large scale as a feed additive with an estimated worldwide output of 200 – 300 t/a. Calcitriol (**6**), 1,25-dihydroxycholecalciferol, (5*Z*,7*E*)-9,10-secocholesta-5,7,10(19)-triene-1α,3β,25-triol, is used as a drug against renal osteodystrophy. Since the daily dose for calcitriol is only 0.25 µg, the worldwide production of **6** including 1α-hydroxy vitamin D_3 comes up to ca. 25 kg/a.

The efficiency of the photochemical step in the vitamin D_3 manufacturing process depends on irradiation of the bromine-free starting material **1b** after having introduced the 7,8 double bond into chlolesterol by bromination and dehydrobromination. When more than 400 ppm bromine- containing byproducts are present, the irradiation time must be prolonged by about

20 % to reach the same conversion as with pure **1b**. This is because the photochemical ring B opening proceeds via the (π, $\pi*$) excited singlet state. The heavy bromine atom accelerates intersystem crossing to the corresponding triplet state. Formation of previtamin D_3 (**2b**) is thus delayed and undesired byproducts appear in the reaction mixture.

As outlined in Section 3.5, it is not economical to perform quasi-stoichiometric photoreactions in highly diluted solutions. Thus, the vitamin D_3 manufacturing process involving photoreaction with 1 – 2 wt % **1b** in ether, tetrahydrofuran, 1,4-dioxane, or ethanol which is commonly stated in the literature does not reflect the present state of the art. In fact, **1b** is sparingly soluble in most solvents, especially in methanol. In order to achieve high concentrations (Section 3.5), solutions containing 5 wt % **1b**, e.g., in *tert*-butyl methyl ether, are irradiated with 20 kW mercury medium pressure lamps in falling film photoreactors similar to that in Figure 8. The high concentration of **1b** reduces the thickness of the photoreaction zone l' (Section 3.1), resulting in exchange of the reactants out of and into the reaction zone by diffusion. For this reason the flow along the light-emitting part d of a 20 kW lamp (see Fig. 10), which is 152 cm long, has to be adjusted to a residence time < 5 s. To avoid overirradiation products, the total conversion of **1b** should be kept below 40 %. In a falling film photoreactor the residence time is limited to a minimum of 3 s, corresponding to the maximum flow rate of ca. 160 L/h. Thus, increased production capacity cannot be achieved by using stronger lamps. The length of the light-emitting part of a 40 kW mercury lamp is also 152 cm and that of a 60 kW lamp is 200 cm (see Table 5). The only way to increase previtamin D_3 output is to multiply the aforementioned photoreaction unit working with 20 kW lamps connected in series or in parallel. Protic solvents should not be used since they are unable to dissolve **1b** sufficiently. They also add photochemically to previtamin D (D_2 and D_3) and even more so to the corresponding tachysterols [19] leading to byproducts which reduce the yield of the final product vitamin D.

5.3. Photoreactions in Supercritical Fluids

Humulones (α-acids) and lupulones (β-acids) are constituents of hop and are of great importance for giving beer its bitter taste. Lupulones differ from humulones by having a side chain instead of an OH group on C-3 of the six-membered ring. In an industrial process both compounds are extracted from hop using supercritical CO_2. Humulone is photochemically transformed into *trans*-isohumulone via oxadi-π-methane rearrangement (ODMP, see Section 7.4) in supercritical CO_2 as solvent (see bottom of page).

Figure 17 shows the flow sheet of the whole process [20].

6. Photosensitized Reactions

6.1. (*E/Z*)-Isomerization of Tachysterol

In the vitamin D_3 production process (Section 5.2) the most important unavoidable byproduct is (*E*)-triene tachysterol$_3$ (**3b**), usually formed in 12 – 15 % yield. Formerly it was separated from the reaction mixture by Diels – Alder reaction with maleic anhydride and subsequent extraction with NaOH. A double irradiation method was then introduced to reconvert **3b** into **2b** by a photosensitized (*E/Z*)-isomerization. 9-Fluorenone was added as photosensitizer to the reaction mixture resulting from the first irradiation. Afterwards a second irradiation was performed using light of longer wavelengths which

Figure 17. Enrichment of the bitter taste in beer by irradiation of the extract obtained from hop using supercritical CO_2 [20]

is not absorbed by the components of the original reaction mixture. Since only partial (*E*/*Z*)-isomerization occurred, more effective sensitizers such as anthracene were applied [21]. All these photosensitizers can only be eliminated from the reaction mixture by column chromatography, but this method cannot be used for large-scale production of vitamin D_3. To overcome this difficulty liquid polymer-bound anthracene sensitizers were developed which, after photoisomerization of **3b** into **2b**, are precipitated as an oil by adding methanol to the reaction mixture [21]. The starting material **1b** is also sparingly soluble in methanol. Because less than 40 % **1b** is consumed in the first irradiation step, the remaining **1b** would be precipitated together with the liquid sensitizer. Due to this contamination it could not be recycled directly. To prevent additional purification steps, 2-(6-hydroxy-3-oxo-3*H*-thioxanthen-9-yl)benzene sulfonic acid disodium salt was introduced as photosensitizer dissolved in small amounts of methanol (Hoffmann-La Roche process for the production of vitamin D_3). It is very effective in the (*E*/*Z*)-isomerization of **3b** and has the advantage that it can be separated from the final photoreaction mixture by extraction with water [22]or by ion exchangers. The photosensitized transformation of tachysterol **3b** into previtamin D_3 reduces the tachysterol content in the final product vitamin D_3 (**2b**) only to 1 %, whereas the aforementioned Diels — Alder reaction with maleic anhydride and subsequent extraction with aqueous NaOH decreases the tachysterol content to 0.1 %.

6.2. Type II Photooxidation

The 16 electrons of O_2 are distributed among the available molecular orbitals. Since triplet states with their parallel electron spins have lower energies than corresponding singlet states with antiparallel electron spins, molecular oxygen has a triplet state as its ground state symbolized by $^3O_2$. Direct absorption of light by $^3O_2$ to produce singlet oxygen, symbolized by $^1O_2$, is forbidden by the Wigner spin conservation rule [23].

Type II photooxidation generally predominates with sensitizers absorbing visible light. Energy can be transferred to $^3O_2$ from both the singlet and triplet excited states of the sensitizer. The triplet state of the sensitizer, however, usually has a much longer lifetime than its singlet state (see Fig. 1). Thus, with very few exceptions photoproduction of $^1O_2$ proceeds via this state:

$$\text{sens}(S_o) \xrightarrow{h\nu} \text{sens}^*(S_1) \xrightarrow{[ISC(S)]} \text{sens}^*(T_1) \xrightarrow{^3O_2} {}^1O_2 + \text{sens}(S_o) \quad (54)$$

Two species of $^1O_2$ exist with different energies. They are symbolized spectroscopically by $^1\Sigma_g$ and $^1\Delta_g$ and their lifetimes are solvent-

Table 7. Three electronic states and selected properties of molecular oxygen

Molecular state	Configuration of $\pi*_{2p}$		Energy, kJ/mol	Lifetime, s		Fluorescence, nm
				Gas phase	Solution	
$^1\Sigma_g^+$	↑	↓	156.9	7 – 12	10^{-9} – 10^{-12}	762
$^1\Delta_g$	↓↑		94.2	45	10^{-3} – 10^{-6}	1268.7
$^3\Sigma_g^-$	↑	↑	0		infinite	

dependent (Table 7). Because of its longer lifetime, only the $^1\Delta_g$ state is dealt with when using the term singlet oxygen ($^1O_2$).

The emission of the $^1\Delta_g$ state in the near IR at 1268.7 nm can be used as physical evidence for the presence of $^1O_2$. Useful chemical evidence is the photooxidative transformation of 2,3-dimethyl-2-butene into 3-hydroxyperoxy-2,3-dimethyl-1-butene which is stable enough to be measured by means of gas chromatography. Furthermore, unlike Type I photooxidations, a sharp reduction in the reaction yield is observed in the presence of 1,4-diazabicyclo[2.2.2.]octane (DABCO) or azide ion due to a sharp reduction of $^1O_2$ production.

Singlet oxygen was discovered in a photochemical experiment performed in 1931 by KAUTSKY. Nevertheless, convincing chemical proof for the existence of an excited oxygen species identical with $^1O_2$ was first found in 1964 by FOOTE and WEXLER. SCHENCK and coworkers previously performed many photooxygenations without recognizing that their oxidizing agent was $^1O_2$.

Sensitizers with a triplet energy $E_T > 95$ kJ/mol are able to transform $^3O_2$ into $^1O_2$ (Table 8). Their solubilities differ according to their chemical structure. Most sensitizers are soluble in protic and/or polar aprotic solvents. The problem of solubilizing anionic dyes such as rose bengal in aprotic solvents can be circumvented by the use of their tetramethylammonium salts or by addition of crown ethers. When strong light sources are applied, rose bengale the most used sensitizer, is rapidly decomposed. Therefore, to assure a constant light absorption a concentrated sensitizer solution must be continuously added to the reaction mixture. Because of its stability, lower molecular mass, stronger absorption, and resistance against acids, the photosensitizer TPP (Table 8) is much better adapted to technical photooxidations than rose bengal, as can be seen from Table 9.

Table 8. Suitable triplet sensitizers for the production of $^1O_2$

Sensitizer	Triplet energy, kJ/mol
Methylene blue	140.2 – 142.3[a]
meso-Tetraphenylporphyrin[b] (TPP)	142.3
ZnTPP	
Hematoporphyrin	155.7
Rose bengal	164.1 – 176.6[a]
Eosin	180.8 – 192.5[a]

[a] Depending upon the solvent used.
[b] 5,10,15,20-Tetraphenyl-21*H*,23*H*-porphyrin.

Table 9. Relevant data of rose bengal and TPP

Characteristic	Rose bengal	TPP

The most convenient method for a rapid and reproducible synthesis of crystalline TPP of high purity from low-priced benzaldehyde and pyrrole is described in [24]. The usefulness of the TPP photosensitized $^1O_2$ production in the presence of acids is exemplified by the preparation of intermediates for the technical syntheses of antimalarial agents which are similar to artemisine, a constituent of the traditional Chinese medicinal herb *Artimisia annua L.Compositae*, known as ″Qinghaosu″ [25]. The following reaction scheme shows how the primarily formed hydroperoxides of methylcarvone are immediately transformed into cyclic hydroperoxides by an acid-catalyzed Michael addition. This method of formation of ″saturated″ cyclic peroxides is remarkable because the 1,4-cycloaddition of $^1O_2$ to dienes leads usually to "unsaturated" cyclic peroxides (endoperoxides, see next page).

Saturated cyclic peroxides

The irradiated solution contains 11.8 % methylcarvone, 18.0 % CH_2Cl_2, 10 % methanol, 0.14 % *p*-toluenesulfonic acid and 0.02 % TPP. The oxidant is air which is bubbled through the solution. To protect the sensitizer TPP against decomposition due to UV radiation, all UV light is eliminated by a liquid cut-off filter with 90 % absorption at 400nm [26]. A 10 kW mercury medium pressure lamp (Fig. 10) transforms 0.3 – 0.4 kg/h methylcarvone into the peroxide mixture.

Various structural evidence confirms the different reactivities of $^3O_2$ (Type I) and $^1O_2$ (Type II); see the following reactions [6], reproduced with permission:

Singlet oxygen is an electrophilic species. Its addition to dienes to generate 1,4-endoperoxides may be viewed as a Diels – Alder reaction with $^1O_2$ as dienophile. In the $^1O_2$ "ene" reaction, olefins containing allylic hydrogens are oxidized to the corresponding allylic hydroperoxides accompanied by 1,2-shift of the double bond. In the final mode, the $^1O_2$ oxygenation of activated double bonds to yield dioxetanes is analogous to the formation of cyclobutanes by a $[2_s + 2_a]$ cycloaddition of two ethylenes.

Singlet oxygenation of conjugated dienes yields different types of endoperoxides depending on the structure of the starting material [6] (the following reactions are reproduced with permission):

From nonhomoannular aliphatic dienes

From homoannular aliphatic dienes

From alkenylarenes and related systems

From heterocyclic dienes

X = O (furan), X = CH_2O (pyran)
X = C(O)O (2-pyrone)

From nonheterocyclic aromatic dienes

The synthetically useful transformations of 1,4-endoperoxides are as follows [6] (reproduced with permission):

In sharp contrast to Type I photooxidations the $^1O_2$ "ene" reaction proceeds stereospecifically in a suprafacial manner with respect to the "ene" unit, i.e., $^1O_2$ attack and hydrogen removal occur on the same side of the olefin [6] (the following reaction is reproduced with permission):

When applying the $^1O_2$ "ene" reaction to pure enantiomers of chiral olefins no racemization is observed. Also (*E*/*Z*)-isomerization does not occur during the course of an "ene" reaction. This stereospecifity makes allylic functionalization by $^1O_2$ attractive to synthetic chemists; its regiospecifity is also useful. Singlet oxygen approaches the substrate predominantly from the sterically less hindered side. Also, in contrast to Type I photooxidations allylic hydrogen abstraction by $^1O_2$ in an "ene" reaction proceeds independently of whether the H atom is a primary, secondary, or tertiary one. As an electrophilic species, $^1O_2$ is sensitive to the nucleophilicity of the olefinic bond. As a general rule, alkyl substitution increases the reactivity of olefins 10 to 100 fold per group. Some of the possible transformations of allylic hydroperoxides, including a silatropic reaction to give an allylic silyl peroxide, include the following [6] (reproduced with permission):

Because of the instability of hydroperoxides in general and of their allylic derivatives in particular, it is common to reduce them to the corresponding alcohols prior to workup and isolation. Unstable hydroperoxides can also be reduced in situ with excess phosphite, especially with $(PhO)_3P$, which reacts quite sluggishly with $^3O_2$ or $^1O_2$, and is in this case the reagent of choice.

The acid-catalyzed heterolysis of the peroxide bond is also depicted in the above scheme; this reaction is known as Hock cleavage and results in the formation of two carbonyl fragments. The base-catalyzed Kornblum – DeLaMare dehydration yielding *α,β-unsaturated ketones*– a synthetically useful transformation–is also shown in this scheme.

A general route to *1,2-dioxetanes* is the cycloaddition of $^1O_2$ to enol ethers, enamines, and other electron-rich alkenes. The following reactions (reproduced with permission) demonstrate the cycloaddition of $^1O_2$ to enamines and the possible transformations of the resulting 1,2-dioxetanes [6]:

Nonluminescent reactions of isolable dioxetanes proceed via catalytic cleavage to give 1,2-dicarbonyl or 2-hydroxycarbonyl compounds. The O – O bond can also be reduced by insertion of, e.g., trivalent phosphorus compounds leading to phosphoranes.

Photosensitized formation of $^1O_2$ from air is one of the cleanest and most convenient methods for the introduction of oxygen functionalities into unsaturated hydrocarbons. Thus, it is expected that $^1O_2$ will be utilized by industry more intensively in the future. Oxygenations using $^1O_2$ are already applied in the manufacturing processes of fragrant chemicals, e.g., of rose oxide and nerol oxide [6] (the following reactions are reproduced with permission):

7. Selected Useful Photoreactions

7.1. Enamide Cyclization

A variety of alkaloids and many pharmacologically active compounds related to them have been synthesized mostly via routes such as Diels – Alder reactions. Enamide photocyclization provides a facile and stereoselective approach for forming compounds such as phenanthridine, benzo[c]phenanthridine, aporphine, protoberberine, and yohimbine alkaloids, and others which were previously accessible only from natural sources. Photochemical formation of a typical basic structure is as follows:

Acrylanilides, enaminoketones, and benzanilides exhibit analogous photochemical behavior. Photocyclization of benzanilides proceeds only under oxidative conditions, e.g., in the presence of I_2 or $^3O_2$.

7.2. Cyclobutane Formation

The photoinduced [2 + 2] cycloaddition of alkenes is important for organic synthesis. The significance of this reaction is derived in part from the stereochemical control for synthesis which enables conjunction of two alkenes to produce a cyclobutane with up to four stereogenic centers:

Regioselectivity is a crucial factor in intermolecular [2 + 2] photocycloaddition, because the photoreaction between unsymmetrical olefins can lead to sixteen products. In some systems, photocycloaddition produces a complex mixture of products. It was, however, soon discovered that substituents can control the regioselectivity to some extent. The intramolecular [2 + 2] photocycloaddition offers many advantages over its intermolecular counterpart. In general, the excited state subunit is more efficiently trapped, and constraints introduced by the intramolecular nature of the reaction frequently allow for greater control over the regio- and stereochemical course of the reaction. Therefore, the intramolecularity of the reactions serves to regulate stereoinduction, regioselectivity, and endo – exo selectivity. The versatility of this reaction is seen in representative studies involving syntheses of small, medium, and large rings as well as of bridged and spirocyclic systems such as longifolene, epi-bulnesene, pentalenic acid, epi-precapnelladiene, hibiscone C, isoamijiol, $\Delta^{9(12)}$-capnellene, β-panasinsene, α-acoradiene, and phoracantholide [6]. The [2 + 2] photoadduct can undergo ring expansion, ring contraction, and one- or two-bond cleavage reactions:

7.3. Oxetane Formation

The light absorbing species responsible for oxetane formation

(Paterno – Buchi reaction) is usually the carbonyl group. A bimolecular reaction is one of the several known paths for nonradiative decay of an excited carbonyl species. Carbonyl compounds produce triplet excited species in high yield on excitation by ISC(S). Due to short singlet lifetimes for carbonyl compounds, triplet states are more likely to be involved in bimolecular reactions. For singlet bimolecular reactions, simple aliphatic aldehydes and ketones are used more than α,β-unsaturated carbonyl compounds. The electronic structure of excited carbonyl groups dictate that the $(n, \pi*)$ reagent acts as an electrophilic radical. Thus, the excited carbonyl can be defined as an "umpolung" reagent, i.e., a reactant having a reverse electronic structure with respect to the functional group that it represents (in this case the carbonyl ground state).

Oxetanes have a variety of potential uses. Photoreactions leading to carefully selected oxetanes are impressive tools in the construction of complex molecules. Among the classes of interesting target compounds are chemicals with pronounced and specific biological activity such as drugs, crop protection agents, and fragrants. Perhaps more interesting to the synthetic chemist is the role of oxetanes as intermediates. The combination of a basic site and ring strain produces the driving force for a variety of selective transformations. Electrophiles (E^+) and nucleophiles (N^-) react with the oxetane yielding ring opening.

Regioselective cracking can take place; heterolytic cleavage providing an intermediate for reaction with dipolarophiles is also possible.

7.4. Oxadi-π-Methane Rearrangement

Triplet sensitization of β,γ-unsaturated ketones causes them to rearrange to cyclopropyl ketones via a formal 1,2-acyl shift. This photosensitized reaction is designated oxadi-π-methane (ODPM) rearrangement and occurs from the lowest excited $(\pi, \pi*)$ triplet state of the β,γ-unsaturated ketone. The reaction path can be described by a sequence of biradical intermediates:

The reactive triplet of the β,γ-unsaturated ketone corresponds to an energy level of ca. 289 – 310 kJ/mol. This means that sensitizers with triplet energies equal to or above 310 kJ/mol must be applied, e.g., acetophenone or 2-propanone, using light with $\lambda > 300$ nm.

Chemical yields are high (86 – 91 %), provided that the conversion of the starting enone is in the range 94 – 96 %. The reaction is most effective in 2-propanone, since the latter serves as solvent and also as sensitizer, making workup easy. However, the substrate concentration in 2-propanone should not exceed ca. 4 wt %, because competitive direct light absorption by the starting material itself leads to an undesired 1,3-shift via Norrish Type I cleavage. Additionally, enhanced light absorption of the starting material lowers the yield of the photoproduct to about 34 % when the 2-propanone solution is irradiated with 254 nm light.

The ODPM rearrangement of bicyclic bridged substrates is enantiospecific. Enantiomeric target materials can thus be obtained by simply choosing the appropriate optically pure precursors to be irradiated. One application is the approach of *cis*,*anti*,*cis*-tricycloundecane type targets e.g., antitumor- and antibacterial-active (–)-coriolin.

7.5. 1,3-Dipolar Cycloaddition

Photolysis of 2*H*-azirines, particularly that of 3-aryl-2*H*-azirines, produces intermediates of the nitrile ylide type which react with numerous electron-deficient alkenes or alkynes as well as with carbonyl compounds, heterocumulenes, and activated esters to yield a variety of five-membered heterocycles [27]. Addition of activated carbon – carbon double bonds to the photochemically generated nitrile ylides forms 1-pyrrolines, whereas addition of carbonyl compounds yields 3-oxazolines:

Although the light absorption of 3-aryl-2*H*-azirines above 300 nm is weak, they react rapidly with the aforementioned components when they are irradiated with a mercury medium pressure lamp through pyrex glass. This method is especially advantageous because the photoproducts absorb at shorter wavelengths, and are thus protected from subsequent photoreactions by the pyrex cutoff filter.

8. Photochemical Wastewater Purification

Vacuum Ultraviolet (VUV) Process. The VUV process is limited to the strong UV absorption bands of oxygen, e.g., in air at 190 nm. Excitation in the VUV spectral region leads in most cases to a homolysis of chemical single bonds and became feasible with the availability of excimer light sources (Fig. 11) which emit in this UV range. Besides photohomolysis of the target substance, VUV photolysis of H_2O generates very efficiently hydroxy radicals (Eq. 55) which then attacks the dissolved or dispersed substrate.

$$H_2O \xrightarrow{h\nu} 1/2\,H_2 + HO^{\bullet} \qquad (55)$$

Xe excimer lamps can be used for water photolysis on a preparative scale [28]. Suitable reactors were developed for the VUV production of ultrapure water for pharmaceutical and microelectronic industries. Disadvantages are the short penetration depth of the VUV (several μm) and the maximum electrical power input of 1.5 kW what makes xenon excimer lamps less suitable for ground and wastewater decontamination.

H_2O_2 – UV Process. Efforts using the Hg emission at 254 nm, produced in particular by low pressure mercury lamps, demonstrate that irradiation at 254 nm is not effective in removing organics from water. However, this kind of radiation is quite efficient for disinfection purposes. In contrast, oxidation by a combination of UV light and H_2O_2 implies the generation and subsequent reaction of hydroxy radicals which perform very successfully the desired mineralization of organic pollutants. A suitable technical arrangement is shown in Figure 5. The oxidation potential of hydroxy radicals (2.80 V) is only outmatched by that of fluorine (3.03 V). Although short-lived, the hydroxy radical is capable of oxidizing organic compounds by hydrogen abstraction (Eq. 56). This generates organic radicals which form peroxy radicals by addition of molecular oxygen (Eq. 57). These intermediates initiate thermal (chain) reactions of oxidative degradation, finally leading to CO_2, H_2O and inorganic salts. Therefore, the photooxidative degradation (mineralization) of organic pollutants is accelerated when the temperature of the irradiated wastewater is increased [29]. However, at temperatures above 70 – 80 °C the light output of medium pressure mercury lamps not only decreases but is also shifted to longer wavelengths. Thus, the temperature of the lamp encircling polluted water should not exceed 70 °C.

$$HO^{\bullet} + RH \longrightarrow R^{\bullet} + H_2O \qquad (56)$$

$$R^{\bullet} + O_2 \longrightarrow RO_2^{\bullet} \qquad (57)$$

$$RO_2^{\bullet} + RH \longrightarrow ROOH + R^{\bullet} \qquad (58)$$

$$ROOH \xrightarrow{\Delta} RO^{\bullet} + HO^{\bullet} \qquad (59)$$

In the H_2O_2 – UV process the rates of degradation increase with increasing H_2O_2 concentration and UV light intensity and are highly dependent on the chemical struc-

ture of the substrates. The reactivities of volatile organic halogen compounds are in the order of $Cl_2C{=}CCl_2 > Cl_2C{=}CHCl > CHCl_3 > CH_2Cl_2 >$ (benzene) > chlorobenzene > chlorophenol > $Cl_2HC\text{-}CHCl_2 > CCl_4$. Chlorine is abstracted and converted into chloride, indicating that the chlorinated structures were destroyed. The use of H_2O_2 is advantageous compared to other methods of photooxidative water treatment: The oxidant is available commercially, it can be stored safely, and is infinitely soluble in water. Hydrogen peroxide is a very cost-effective source of hydroxy radicals and the procedure of water treatment with H_2O_2 is simple. A disadvantage is the rather low absorption coefficient of H_2O_2 at 254 nm. A higher percentage of hydroxy radical formation may be obtained using Xe-doped mercury light sources exhibiting a strong emission at 210 – 240 nm, where the absorption coefficients of H_2O_2 are considerably higher. A further disadvantage exists in the efficient trapping of hydroxy radicals by HCO_3^- and CO_3^{2-} ions (Eqs. 60 and 61).

$$HO\cdot + HCO_3^- \longrightarrow H_2O + CO_3\cdot \quad (60)$$
$$HO\cdot + CO_3^{2-} \longrightarrow HO^- + CO_3\cdot \quad (61)$$

Although the generated carbonate radical anions are oxidants themselves, their oxidation potential is less positive than that of hydroxy radicals. By this way a certain selectivity may be introduced with respect to the compounds to be degraded (i.e., those compounds that are less prone to oxidation will not be attacked) [30].

Ozone – UV Process. Ozone has a much higher light absorption than H_2O_2, and the inner filter effects, e.g., by aromatics present in the wastewater, play a minor role. On the other hand, the low solubility of ozone in water together with the necessity to install further apparatus for ozone production represent additional problems in the technical application of the O_3 – UV process. In general, the photolysis of ozone dissolved in water leads to the production of H_2O_2 (Eq. 62)

$$O_3 + H_2O \xrightarrow{h\nu} H_2O_2 + O_2 \quad (62)$$

Finally, by a sequence of reactions including the interaction of organic substrates present in the water, HO· radicals are also formed in the O_3 – UV process.

The analytical control determines the total organic carbon in milligrams per liter treated water. For this purpose, a wastewater sample is led in a stream of oxygen over a catalyst, e.g., Pt/SiO_2. Here, the organic water pollutants are quantitatively oxidized to CO_2. The subsequent determination of CO_2 can be performed in many ways, e.g., with an infrared detector.

Abstract

The article contains sections titled:

1. Introduction
2. External Photoeffect
3. Internal Photoeffect
4. Applications
4.1. Light Sensors and Detectors
4.2. Solar Cells
4.3. Imaging Systems

Photoelectricity is one of the key phenomena of today's imaging and communication technologies. In general, photoelectricity is understood as the interaction of photons with solids, resulting either in a liberation of electrons (external photoeffect) or in an enhanced electrical conductivity (internal photoeffect). Both effects are discussed particularly with regard to the basic principles and materials involved.

Photoelectricity with its link between light flux and electrical current was the basis for a huge technical and scientific effort directed to enhance, extend, and diversify devices in their functions as light sensors and detectors and later as image pick-up systems which enable transmission, processing, display, and printout of the received optical information; e.g., solar cells and sensor arrays for digital still and video cameras.

[Top of Page]

1. Introduction

Generally photoelectricity is understood as the interaction of photons with solids, resulting either in a liberation of electrons (*external photoeffect*) or in an enhanced electrical conductivity (*internal photoeffect*).

Depending on the spectral range of the interacting electromagnetic radiation various different photoeffects are observed (Table 1).

Table 1. Radiation and photoeffects

Radiation	Photoeffect
High energy γ-radiation, > 1 MeV	photoproduction of electron – positron pairs
γ-Radiation	nuclear photoeffect, Auger effect
Low energy γ-radiation or X-rays	ionization of atoms or molecules
UV-light	external photoeffect
Visible and infrared light	internal photoeffect, photoconductivity

The *external photoeffect* was detected in 1887 by HALLWACHS. The following studies of LENARD (1899 – 1902) on the material and wavelength dependence of this phenomenon and its explanation by EINSTEIN in 1904 gave a significant impulse to the development of modern quantum theory.

Further work on photoemission from metal surfaces resulted not only in a good understanding of the mechanism itself but lead also to applications such as vacuum photocells, photomultipliers, vidicon tubes and in addition to the exciting new analytical method of photoelectron spectroscopy for materials research and surface analysis (⟶ Surface and Thin-Film Analysis, ⟶ Surface and Thin-Film Analysis – Ultraviolet Photoelectron Spectroscopy (UPS)).

The *internal photoeffect* — light impact on a solid state material gives rise to a higher current of electrons — was observed by HITTORF on selenium early in 1852. However, until 1930 these experiments were ignored as being not reproducible and therefore of little scientific value.

Finally, the publications of GUDDEN, POHL, HIELSCH, and STÖCKMANN between 1928 and 1947 draw the attention to photoconductivity as a common property of insulators and semiconductors.

From that time up to now the investigation of photoconductivity has proved to be a useful tool to understand the physics of the solid state.

In parallel to these basic studies a broad variety of technologies and devices utilizing the effect of photoconductivity have been brought into application.

[Top of Page]

2. External Photoeffect

Electrons released by incident light can escape from a solid if the photon energy $h\nu$ is equal or higher than a given minimum energy E_0 which is a material characteristic. Furthermore, the kinetic energy E_{kin} is independent of the light intensity, but a linear function of the photon energy. The energy balance is given by the Lenard – Einstein equation:

$$h\nu = E_0 + E_{kin} \quad (1)$$

E_{kin} represents the maximum kinetic energy observed in the emerging electron flux. It may be lowered by collision processes in the surrounding atmosphere.

The external photoeffect was first observed with metals. Later work showed that certain semiconductors offered much higher photoemissive yield and a response to smaller photon energies than metals.

The minimum energy E_0 which light must possess to liberate an electron depends on the type of bonding encountered. In the case of metals E_0 is practically equal to the electron work function E_w (Fig. 1) which is in the order of several electron volts [3].

Figure 1. Electron energy level diagram for photoemission of an electron from a metal (A) and a semiconductor (B)

Thus, in the case of metals, the external photoeffect is primarily a phenomenon of the ultraviolet and visible region. The work functions (Table 2) are correlated with the position of the corresponding metals in the periodic table [4].

Table 2. Work functions and threshold wavelength of some metals

Metal	Work function, V	Threshold wavelength, nm
Cesium	1.94	639
Sodium	2.29	541
Barium	2.56	484
Magnesium	3.67	338
Chromium	4.37	284
Tungsten	4.54	274
Copper	4.36	284
Platinum	5.55	223

In semiconducting materials, the existence of a forbidden gap E_g between an almost filled valence band and an almost empty conduction band gives conditions for the photoeffect which differ considerably from the behavior of metals. The most significant feature of semiconductors is the absence of inelastic scattering between electrons. Thus, in contrast to the metallic transport processes, the photoelectrons in semiconductors encounter energy losses only by lattice scattering, i.e., phonon generation. Since much lower energy losses are involved in this case, the photoemissive yield can be high. However, to obtain a high photoemissive yield, a sufficiently small electron affinity E_a is required, which is the energy difference between the vacuum level and the bottom of the conduction band E_c. If the gap $E_g = E_c - E_v$ (E_v top of the

valence band) is reasonably larger than the electron affinity, the probability to escape from the semiconductor is high enough for most of the photoelectrons even after inelastic collisions with phonons. Thus the range in which the electrons are able to escape corresponds to the penetration depth of the incident light (Fig. 1). Therefore, quantum efficiency can be close to the theoretical maximum, if reflection losses of light are taken into account. Compounds with such a high quantum efficiency include several alkali antimonides such as Cs_3Sb and Na_2KSb (see Table 3), and certain I – VI compounds such as Cs_2Te and Rb_2Te. They have practical importance as photocathode materials [4].

Table 3. Band gap E_g, electron affinity E_a, and photoemissive yield of alkali antimonide photocathodes

Material	E_g, eV	E_a, eV	Quantum efficiency, electrons/photons
Cs_3Sb	1.6	0.45	0.30
Na_2KSb	1.0	1.0	0.30
$[Cs]Na_2KSb$	1.0	0.7	0.40

[Top of Page]

3. Internal Photoeffect

The variation of electrical conductivity with the intensity of incident light, called photoconductivity, is the result of an internal photoeffect in which carriers are excited by radiation energy from lower to higher energy levels, supposed the quantum energy is high enough to cause the transition. To observe photoconductivity, however, the number of carriers generated by light must be measurable in comparison to the free carriers normally available in the material. This is the reason why photoconductivity is not observed in metals. As mentioned above, selenium was the first material in which photoconductivity was detected.

However, since no suitable technology was available to purify the material and to grow crystals with defined structure, it took nearly 100 years before an intensive study on the internal photoeffect started. The studies were carried out on crystalline covalent solids such as silicon, germanium, III – V and II – VI compounds, e.g., InSb, GaAs, PbS, CdS, and resulted in a fundamental understanding of the phenomenon, including a description of the role of defects and impurities, which control carrier lifetime and hence photoconductor characteristics. Other important areas of investigation dealt with the complex issues of surface states including chemical and physical adsorption. The studies benefited from the advances in experimental techniques of surface analysis such as X-ray and UV photoelectron spectroscopy and Auger electron spectroscopy.

Subsequently, attention turned to disordered systems such as amorphous solids, molecular solids, molecular doped polymers, and liquids.

All these different materials have in common that the conductivity depends on the number of photogenerated carriers. When the light is switched on, the conductivity at first increases linearly with time until saturation is reached because of the fact that carrier recombination occurs after a lifetime τ.

For stationary illumination of a sample where the light is uniformly absorbed the number of photoelectrons Δn amounts to

$$\Delta n_e = \eta_e \cdot n_{phot} \cdot \tau_e \quad (2)$$

the corresponding change in the electrical conductivity σ is:

$$\Delta\sigma = e_0 \cdot \eta_e \cdot n_{phot} \cdot \tau_e \cdot \mu_e \quad (3)$$

where η_e is the photoelectric yield, n_{phot} the number of absorbed electrons, μ_e the mobility of the electrons and τ_e denotes the time span in which the excess carriers contribute to the photoconductivity before they recombine or are trapped in impurity centers.

Excitation may take place either across the energy gap between the valence band and the conduction band, or alternatively via intermediate energy levels due to the presence of impurities which may be either donors or acceptors.

Photoconducting materials of the first type are known as intrinsic photoconductors (Fig. 2), those of the second type extrinsic photoconductors (Fig. 3) [5]

Figure 2. Band to band transitions in direct (A) and indirect (B) semiconductors

In indirect semiconductors, e.g., c-Si the transition is phonon assisted.

Figure 3. In an extrinsic semiconductor acceptor or donor levels exist in the band gap and photons can cause transitions to these levels. The threshold energy for the transition is normally smaller than the gap.

The long wavelength threshold of most *intrinsic photoconductors* is in the range between 0.5 and 10 µm (Fig. 4). An exception exist with a mixture of HgTe and CdTe compounds to form an intrinsic photoconductor which, depending on composition has an adjustable threshold between 0.8 and 40 µm [5]. The alloy systems GaAsP, InGaAs, and InGaAsP can be tailored to respond at a wavelength range from the visible up to 1.5 µm. But the choice of semiconductor materials for detectors is limited to those that match the available substrates on which the active devices are grown. Substrates with adequate quality, technical sizes, and reasonable costs are Si, GaAs, Ge, and InP. The most widely used detector material for long haul communication is InGaAs for λ = 1.55 µm and InGaAsP for λ = 1.55 µm and λ = 1.3 µm. Both detector materials match very well with InP substrates.

Figure 4. Band gap and cutoff wavelengths of several semiconductors

In *extrinsic photoconductors*, presence of donors or acceptors requires activation energies which are by an order of magnitude, or more, lower than the energy gap, resulting in a sensitivity to medium or far infrared radiation. However, the photoelectric yield is significantly smaller since the impurities must necessarily be diluted by a factor of 10^4 – 10^7 in the host material (Table 4).

Table 4. Ionization energies and cutoff wavelengths for doped germanium and silicon

Semiconductor	Impurity	Ionization energy, eV	Wavelength cutoff for detection, µm
Ge	Au	0.15	8. 3
	Cu	0.041	30
	Zn	0.0333	38
	B	0.0104	120
Si	In	0.155	8
	Bi	0.0706	18
	B	0.044	28

In contrast to crystalline semiconductors the photoconductive phenomenon in amorphous solids, molecular solids, and liquids show quite different features. In the amorphous or disordered state the concept of allowed energy bands is no longer valid. Here, excitations localized on individual atoms or molecules, intramolecular relaxation and electron – phonon interaction play the dominant role. Activities in this field are increasing, not only because of scientific interest but also under the aspects of technical applications for electrophotographic imaging and solar cells, since these materials offer the possibility to manufacture large area photoconductors either by vacuum deposition, chemical vapor deposition, or cast of films from solutions [6].

In order to use photoconductivity as a tool to investigate excitation mechanism and electrical transport parameters experiments have to performed under special conditions or together with other independent experiments. The dependence of the photoconductivity on the wavelength under stationary illumination gives information whether intrinsic or extrinsic transitions are involved. In some cases the number of photoelectrons Δn_e and the drift mobility μ_e whose product appears in Equation 3 can be determined separately by Hall effect and electron spin resonance.

The response of a photoconductor to pulsed or modulated light allows to evaluate the lifetime and the mobility of the majority carrier. A very powerful kind of pulsed photoconductivity measurement is the “time of flight” method which enables the observation of the transit of a group of charge carriers through the photoconductor. Thus from a single experiment of this type the polarity, density, and drift mobility of the charge carriers can be determined. Fig. 5 shows the experimental

configurations mostly used to investigate transient photoconductivity in disordered materials such as amorphous and molecular solids. The sample is sandwiched between electrodes. Through the upper one a short pulse of strongly absorbed light excites a thin layer of carrier pairs. Depending on the direction of the electric field either electron or holes will be drawn into the bulk and if carrier lifetime permits, they will reach the opposite electrode in the transit time t_T. From t_T the carrier mobility μ can be calculated. The time constant of the external circuit, RC' determines whether a rectangular pulse (upper part of Fig. 5 A) or its integral (upper part of Fig. 5 B) can be observed. A rectangular pulse is only expected for semiconductors in which a unique mobility or mean velocity per unit field defines the drifting charge sheet. For disordered systems the analysis of the carrier transport signal as obtained from the experiment is more complex but very still useful to investigate the transport phenomenon. Another experimental configuration of the time of flight method uses a corona charging of the photoconductor instead of a transparent counterelectrode (lower part of Fig 5). This arrangement closely resembles the experimental conditions in typical applications of high resistivity photoconductors such as in electrophotography or vidicon tubes. The surface potential V is monitored by an electrostatic probe. The light pulse which is absorbed in a narrow region below the surface results in the transfer of the charge Q to the bottom contact producing a linear drop in the surface potential V. The transit time can be obtained from either V (lower part of Fig 5 A) or its derivative (lower part of Fig. 5 B).

While pulse excitation is usually easier to implement in practice, step-function excitation (Fig. 5 C) also allows determination of the transit time t_T. Typical transit times are in the order of nanoseconds for amorphous silicon and selenium and in the range of micro- to milliseconds for molecularly doped polymers which are caused by the low mobilities (Fig. 6) [7], [8].

Figure 5. Time of flight method

4. Applications

Photoelectricity with its link between light flux and electrical current was the basis for a huge technical and scientific effort directed to enhance, extend, and diversify devices in their functions as light sensors and detectors and later as image pick-up systems which enable transmission, processing, display, and printout of the received optical information.

4.1. Light Sensors and Detectors

Table 5 gives a summary of commercial photoelectric devices, their technology, composition, structure and application. It is beyond the scope of this article to describe each of the devices in detail. They are treated extensively in the standard textbooks on electronic or optoelectronic devices [9], [10].

In the following emphasis is being put on solar cells and imaging systems.

Table 5. Light sensors and detectors

Device	Photoeffect	Material	Application
Photocell	external	alkali, multialkali or semiconductor photocathode in vacuum tube	measuring of light intensity short response time ≈ ns
Photomultiplier	external	as above, but higher sensitivity by additional dynode chains for secondary electron emission. Gain up to 10^8	measuring of weak light intensities photon counting, response time ≈ ps – ns
Photoconductor	internal intrinsic and extrinsic	photoconductive material (Fig. 3) between ohmic contacts	measuring of light intensity, visible to far infrared
Photodiode	internal/intrinsic	silicon, germanium *p-n*, *p-i-n*, M-S[a] structures	measuring of light intensity in the photovoltaic mode as solar

			cell (⟶ Photovoltaic Cells) light detector in fiber optics
Phototransistor	internal/intrinsic	silicon *p-n* photodiode as base-collector in a bipolar transistor or MOSFET[b]	measuring of weak light intensities light controlled switch of electrical power optoelectronic coupler
Photothyristor	internal/intrinsic	silicon	switching of high voltage and high currents

[a] M-S = Metal-semiconductor.
[b] MOSFET = Metal-oxide semiconductor field-effect transistor.

4.2. Solar Cells (⟶ Photovoltaic Cells, ⟶ Solar Technology – Photovoltaic Systems)

A solar cells is basically a large-area photodiode operated in the photovoltaic mode, where upon illumination the diode feeds electrical energy into an external load. In principle the solar cell consists of a depletion layer (*p-n* or *p-i-n* junction). *p* (base) and *n* (emitter) regions are connected to the external load by ohmic contacts. In order to achieve maximum illumination of the active zone the front contact to the emitter has to be very small and the free surface of the emitter must be covered by an antireflex coating (Fig. 7).

Figure 7. Schematic of a solar cell

Photons, whose energies are equal or higher than the band gap of the semiconductor are absorbed in the cell and generate electron – hole pairs which are separated by the electrical field across the *p-n* junction. Electrons and holes are accumulated in the *p*- and *n*-region giving rise to a photovoltage across the external contacts which is known as open circuit voltage V_{OC} [5] (Fig. 8).

Figure 8. Schematic of a *p-n* diode and the minority carrier concentration in absence and presence of light. The minority charge goes to zero at the depletion region edge due to the high field which sweeps the charge away.

The equilibrium minority charge is p_n and n_p on the *n*- and *p*-sides respectively.

At high light intensities V_{OC} can approach E_g/e_0. In the case of Si solar cells V_{OC} is roughly 0.7 V. A plot of the photocurrent as a function of photovoltage provides the curve shown in Figure 9. The point of maximum power output P_m can be taken from that curve to calculate the conversion efficiency η of a solar cell, defined as the ratio of the output electrical power P_m to the input optical power P_{in}. Efficiency depends quite critically on the match of the band gap E_g to the solar energy spectrum. Photons with energy lower than E_g will not produce electron – hole pairs, whereas photons with energies greater than E_g generate only electrons and holes of the same energy E_g regardless of the amount of excess energy. The excess energy is dissipated as heat and may contribute to the decrease of efficiency by warming up the device.

Figure 9. The relationship between current and voltage delivered by a solar cell

V_{OC} = open circuit voltage, I_{SC} = short circuit current

From this point of view GaAs-based solar cells are better matched to the solar spectrum and provide greater efficiencies than Si-based cells. However they are more expensive than Si technology but very useful when high efficiency and stability against cosmic radiation as for example in space applications are required.

Shockley and Queisser [11] calculated in 1961 an upper limit of 30% for the yield outside the atmosphere und 33% inside for unfocussed sunlight. Peak values for c-Si cells from lab production are currently at 24,7% , which is about 75% of the maximum achievable.

Up to now, only solar cells on the basis of c-Si and a-Si have reached the status of commercial industrial production. But yields are to low and costs of production are still to high to compete with fossil energy. It is expected that by using thin-film

technologies production costs can be reduced significantly, assumed that yields remain adequate. First thin-film a-Si and CIS cells from pilot plant promise a yield of 11% and ever higher.

Table 6 gives a summary of efficiencies of commercial cells and lab samples of various materials and technologies.

Table 6. Efficiency of current solar cell technologies

Material	η, %	
	Industrial production	Laboratory production
Crystalline silicon	13 – 17	24.7
Amorphous silicon	7 – 8	13.5
CDTe – CdSe		16.1
$CuInGaSe_2$ (CIS)	11	17.7
GaAs		25.1
GaInP – GaAs, tandem		30.3
GaAs – GaSb, tandem		31.1
TiO_2 – organic dye		10.4

4.3. Imaging Systems

In principle imaging systems consist of a device that captures an image and converts it into electrical signals, processes and transmits the image, and finally displays it or records it on archivable media.

On both sides — image pick up and recording — photoelectric devices contribute as key components (Table 7).

Table 7. Photoelectric devices in imaging systems

Device	Used in
Photodiodes	drum type image scanners
Photocells	
Photomultipliers	
Photoconductive semiconductors materials	target in TV pick up tubes
Highly integrated charge coupled devices (CCD)	one or two dimensional sensor arrays; flatbed image scanners, fax machines, digital copiers, digital photographic cameras, TV-cameras, and camcorders
Photoconductive layers of amorphous chalcogenides and silicon and molecularly doped polymers	photoceptors in office copiers, nonimpact printers, and plain paper fax machines

In highly integrated image pick-up systems for video cameras and digital photo cameras, charge coupled device (CCD) sensors and complementary metal oxide semiconductors (CMOS) are widely used.

The basic steps of a CCD sensor array are the generation of electrical charge carriers when photons are absorbed, the charge collection at each pixel (picture element), the charge transfer from each pixel to the single output amplifier, and the charge measurement for each pixel.

Charge transfer takes place sequentially by shift registers.

CCDs allow the fabrication of image sensors with up to 8 megapixel in digital photo cameras, exceeding in the meantime the resolution of 35-mm silver halide film. Cameras with CMOS sensors go even beyond this, reaching 16 megapixel on an array size of 24 × 36 mm. CMOS technology integrates charge generating, signal amplification, and read-out functions on each pixel. Common for both types of sensors is that a color filter is used on each pixel to obtain the RGB information for image processing. Usually, the ratio of the number of the filters is R=1, G=2, B=1. The only exception is a special CMOS sensor having three separate pn-junctions at different depths in the device. Color separation occurs by the wavelength-dependent absorption coefficient of silicon [12].

With electrophotography — besides ink-jet printing one of the dominating technologies for production of hard copies output (⟶ Imaging Technology – Electrophotography) — the charge pattern formed by imagewise exposure is developed by charged pigment particles, called toner. The toner image is then transferred and fixed by fusing the toner on the paper. The advantage of this successful imaging process relies on the ability of amorphous chalcogenides, silicon, and molecular doped polymers

1. to hold electrical charge in the dark;
2. to discharge exposed areas efficiently; and
3. to be capable of being fabricated into large-area and defect-free films.

1. History [51–58]

It has been known since ancient times that many substances undergo visible changes on exposure to light. The first attempts to create images with the help of light, however, were reported in 1727 by JOHANN HEINRICH SCHULZE, a German professor of medicine. He glued stencils with letters or words onto a bottle containing a mixture of chalk and silver nitrate, exposed the assembly to sunlight, removed the stencils, and obtained metallic silver images of the stencils in the contents of the bottle. These images could not be permanently fixed in daylight. The first camera images were described in 1802 by an Englishman, THOMAS WEDGWOOD, who used paper or leather moistened with silver nitrate and exposed it in a camera obscura, but these images could also not be fixed.

The earliest surviving photograph is one made approximately 1826–1827 by a Frenchman, JOSEPH NICÉPHORE NIÉPCE. A tin plate coated with photocurable asphalt was exposed for ca. 8 h in a camera obscura, and the unilluminated, uncured areas were removed by washing with a mixture of petroleum and lavender oil (heliography) [51], [53], [56]. In 1829 NIÉPCE commissioned LOUIS JACQUES MANDÉ DAGUERRE to develop the process.

In 1839 DAGUERRE announced the first photographic process having a practicable sensitivity (daguerreotype process). A silver- coated copper plate was treated with iodine vapor to generate a thin layer of light-sensitive silver iodide. After exposure in a camera, the image was rendered visible by treatment with mercury vapor, which formed light-scattering particles of silver amalgam in the areas exposed to light. The image was fixed by bathing in a sodium thiosulfate (hypo) solution, which removed any photosensitive silver iodide still present. At first, the exposure time was ca. 8 – 20 min, but later improvements in the process shortened this to a few seconds.

At about the same time, WILLIAM HENRY FOX TALBOT in England devised a process that he called "photogenic drawing." A paper impregnated with silver chloride, was exposed imagewise for about an hour and black, finely dispersed silver was produced in the illuminated areas (printing-out paper). In 1840 TALBOT created a negative – positive process that could generate several positive prints from a single negative original (calotype). Paper impregnated with silver iodide was exposed for ca. 1 min, developed with a gallic acid – silver nitrate solution, and fixed with a solution of sodium chloride (later replaced by sodium thiosulfate). This negative was made transparent with wax and then used for production of positive copies by exposing silver chloride-impregnated printing-out paper through the negative.

In 1851 – 1880, the "wet collodion process" of the Englishman FREDERICK SCOTT ARCHER found wide acceptance in photography. A glass plate was coated with silver iodide or bromide in cellulose nitrate solution, exposed for ca. 10 s to 1.5 min while still wet, and developed with pyrogallol or iron(II) sulfate. The developing action of iron(II) sulfate was discovered in 1844 by ROBERT HUNT, that of pyrogallol in 1851 by JUSTUS VON LIEBIG. The expensive wet collodion process required a photographic laboratory in a tent on-site, because the plate could not be coated until immediately before use. From 1854 on, a simpler "dry collodion process" devised in France by MARC ANTOINE GAUDIN came into use, but at first the sensitivity of this method was low. The albumen paper created by LOUIS DÉSIRÉ BLANQUART-EVRARD was introduced in 1850; it used egg white to bind the silver chloride grains. Albumen paper gave particularly good tonal reproduction and was favored by professional photographers until around 1930.

A crucial advance took place in 1871 when the English physician RICHARD LEACH MADDOX reported the preparation of a *dry gelatin plate*. The emulsion of silver halide crystals in gelatin is still used in silver halide photography today; at that time, it made the first amateur photography possible by separating the steps of exposure and development. Dry plates were mass-produced since 1877, first in the United Kingdom, later also in other countries (Germany, Austria, the Netherlands) [56].

Flexible backings are easier to handle than plates; paper roll film was introduced in 1884 (GEORGE W. EASTMAN), cellulose nitrate film in 1887 (HANNIBAL GOODWIN), nonflammable cellulose acetate film in 1923, and polyester film, which has a better dimensional stability, in 1955 (Du Pont). A paper backing is still used for photos to be viewed in reflected light; from 1866 to 1969 the paper stock was coated with baryta

(barium sulfate) in order to prevent the image sinking into it. Since 1969, paper stock has been coated with polyethylene on both sides.

Spectral Sensitizers.

The advance of photography depended critically on the discovery of spectral sensitizers by the German HERMANN WILHELM VOGEL in 1873. Unsensitized silver halides are not sensitive to green and red light. Only the discovery of spectral sensitizers enabled the reproduction of all colors in black-and-white photography in a tonally faithful manner; development of spectral sensitizers was also the prerequisite of color photography. VOGEL discovered, e.g., the green-sensitizing action of the triphenylmethane dye corallin. Later research on sensitizers focused on the methine dyes, especially the cyanines. Since 1906, WALTER KÖNIG (Dresden), W. H. MILLS (University of Cambridge), and FRANCES M. HAMER and LESLIE G. S. BROOKER (Kodak) have synthesized and identified many cyanines that have been used as sensitizing dyes. Supersensitization (see Section 2.2.1) was discovered in 1920 by F. FORSTER RENWICK (Ilford).

In 1936 ROBERT KOSLOWSKY discovered that the sensitivity could be enhanced by adding traces of gold salts and thiocyanates to the silver halide emulsion. This "gold effect" made it possible to create the first highly sensitive fine-grained films.

Developers.

At first, exposed silver halide – gelatin materials (plates, films, papers) were developed with an alkaline solution of pyrogallol. Later developers include hydroquinone (WILLIAM DE WIVELESLIE ABNEY, 1880), *p*-phenylenediamine and 4-aminophenol (MOMME ANDRESEN, 1888 and 1891), Metol (ALFRED BOGISCH and JULIUS HAUFF, 1891), and Phenidone (J. D. KENDALL, 1940). The *acidic fixing bath* (sodium thiosulfate, sodium sulfite, acid) now used was devised simultaneously by ALEXANDER LAINER and M. ANDRESEN in 1889.

Around 1940, ANDRÉ ROTT (Gevaert) and EDITH WEYDE (Agfa) independently devised the silver halide diffusion transfer process. During development, unexposed silver halide is dissolved by an Ag^+ complexing agent. These complexes diffuse into an image-receiving layer containing development nuclei, where they form a positive silver image. In 1948, Polaroid (EDWIN LAND) marketed a black-and-white "instant photography" system based on this process, and Agfa and Gevaert created office duplicating materials and offset printing films (→ Imaging Technology, Chap. 2.2.3.).

Color Photography.

The search for true color photography began soon after the invention of photography. Hand-tinting of daguerreotypes and silver halide images were initially used.

The first attempts at color photography did not lead to any practical results. In 1852, HERMANN VON HELMHOLTZ proposed a process based on the color sensation theory of THOMAS YOUNG. JAMES CLERK MAXWELL discovered *additive color photography* in 1855: black-and-white separation images were produced with red, blue, and green filters; the images were converted to transparencies and projected onto the same surface through the same color filters (see Section 5.1). LOUIS DUCOS DU HAURON proposed in 1862 that a screen could be employed for additive color photography. In 1891, GABRIEL LIPPMANN discovered interference color photography in Paris. In this process, a silver halide – albumen coating on a glass plate is exposed while in contact with a mirror-like mercury surface which results in interference phenomena.

The first successful color process was the additive grain screen process, represented by the Autochrome plates (1907) of LOUIS and AUGUSTE LUMIÈRE, the Agfa mosaic plate of 1916, and the Agfacolor mosaic film of 1932. This process was based on the ideas of MAXWELL (additive process) and DUCOS DU HAURON (mosaic). Another additive process, using a lenticular screen, was proposed in 1896 by JULIUS R. E. LIESEGANG and since 1908 further developed by R. BERTHON. Kodak in 1928 and Agfa in 1932 brought lenticular films for amateur cinematography on the market. The Berthon – Siemens color motion-picture projection process – also based on a lenticular screen – was in use in 1936 for a short time (developed by Siemens & Halske and Perutz).

Virtually all modern color processes, however, are *subtractive*, the image being formed with yellow, magenta, and cyan dyes. The subtractive process was discovered in 1868 by L. DUCOS DU HAURON and independently

in 1869 by CHARLES CROS (see Section 5.2.1). Color motion-picture films using colored washed-out reliefs were manufactured in 1922 (Technicolor; see Section 5.5). Other processes based on the principles of washed-out and swollen reliefs were the Pinatype, Duxochrome, and Kodak dye-transfer processes.

The bleach-out process, in which nonlightfast dyes selectively absorb incident light and are thereby decolored, was proposed by LIESEGANG in 1889. It attracted the attention of several researchers (e.g., EMILE VALLOT, KARL WOREL, and RICHARD NEUHAUSS), but never led to a practicable method.

Among the processes utilizing the principle of image formation by dye destruction, only the silver-dye bleach process has become commercially important (see Section 5.4). The principle, proposed by KARL SCHINZEL (1905) and J. H. CHRISTENSEN (1918), was the basis for Pantachrom-Tripofilm (Agfa, 1939), Gasparcolor (according to BELA GASPAR, 1942), the Cibachrome and Cibacopy materials (Ciba-Geigy, 1963) today Ilfochrome (Ilford).

Today's subtractive color films and papers, however, are chiefly based on the principle of chromogenic development, in which the dyes in the image are produced when oxidized color developers react with "dye couplers" (RUDOLF FISCHER, 1911). The first commercial product was Kadachrome narrow-gauge film (1935), which employed dye couplers in the processing baths and controlled diffusion from dye-destroying baths (LEOPOLD MANNES and LEOPOLD GODOWSKY Jr.). The simplified second Kodachrome process, based on selective re-exposure, followed in 1938. Agfacolor transparency film appeared on the market in 1936. Here hydrophilic dye couplers are embedded in separate layers of the material so that they cannot diffuse (GUSTAV WILMANNS and WILHELM SCHNEIDER). The corresponding Agfacolor negative film was marketed in 1939 and Agfacolor paper in 1942. Kodacolor paper and film were introduced in the same year; oil droplets containing the couplers are emulsified into the layers of these materials (EDWIN E. JELLEY, PAUL W. WITTUM). The Ektachrome and Ektacolor films (Kodak), also employing this principle, followed in 1946 and 1948.

Virtually all color films and papers now on the market incorporate hydrophobic couplers in the emulsion.

Today's black-and-white and color materials may utilize inventions dating back several decades, but their sensitivity, sharpness, granularity, color reproduction, and durability far surpass those of the earlier materials. Important contributions include core – shell emulsions (EBERHARD KLEIN and ERIK MOISAR, Agfa, 1962) for high-speed films; the use of development-inhibitor-releasing (DIR) couplers to improve granularity, sharpness, and color reproduction (KEITH E. WHITMORE and coworkers, Kodacolor II film, 1972); and the creation of tabular-grain emulsions to improve sensitivity and granularity (J. T. KOFREN and coworkers, Kodak, 1981).

In 1963, Polaroid introduced a novel subtractive color material (Polacolor) based on a *dye diffusion transfer process*. In the development step, embedded color developers in the exposed regions are oxidized to nondiffusing quinones, while the dye developer from the unexposed regions migrates into an image-receiving material. Kodak in 1976 and Fuji in 1981 followed with a dye diffusion material based on dye-releasing redox compounds (see Section 5.5).

After 1945, color printing materials containing no silver halides were also devised (→ Imaging Technology, Chap. 3.3.4.2.).

2. The Photographic Sensor

2.1. Elementary Process

2.1.1. Basic Principles

In all conventional photographic materials, silver halide microcrystals (grains) serve as both the light-sensitive sensors and the elements for the storage of optical information. Silver atoms are formed upon absorption of electromagnetic radiation or interaction with ionizing particles; these atoms eventually combine to form small nuclei of silver, the latent-image specks. When grains bearing such specks come into contact with a reducing agent (the developer), they are rapidly and completely reduced to metallic silver. Unexposed crystals do not bear such latent-image specks; nevertheless the reduction

of these crystals starts after a considerable delay and leads to the formation of fog. Under usual development conditions, the minimum size of a silver nucleus required for immediate developability is approximately four silver atoms [59], [60]. For larger silver aggregates, the "critical size" r of the aggregate and the redox potential ΔE of the developer can be related by a relation similar to the Gibbs – Thomson equation:

$$r = \frac{2 \cdot \sigma \cdot V_{\mathrm{Ag}}}{F \cdot \Delta E} \tag{2.1}$$

This relation has been confirmed experimentally [61], [62]. Here σ is the specific surface energy of the aggregate, V_{Ag} is the molar volume of silver, $\Delta E = E_{\mathrm{redox}} - E_{\mathrm{Ag^+/Ag}}$ is the difference between the redox potential of the developer and the electrochemical potential of silver, and F is the Faraday constant. It seems certain that a relation similar to Equation (2.1) can appropriately describe the redox properties of extremely small silver clusters down to the size of latent-image specks. However, bulk properties such as radius and surface energy lose their physical meaning for particles consisting of just a few atoms and must be replaced by atomistic properties such as binding energy and dissociation energy [63], [64].

Figure 1. Electron micrographs (SEM) of typical silver bromide microcrystals
Left to right: cubes, octahedra, tabular crystals

2.1.2. The Silver Halide Crystal

Silver bromide and *silver chloride* form lattices with the face-centered cubic (fcc, rock salt) structure. Their equilibrium shape, therefore, is cubic with (100) faces. Under certain conditions, silver bromide in particular may appear in octahedra bounded by (111) planes, for example when crystal growth occurs in the presence of excess bromide ions which are mainly adsorbed to (111) faces [65][66][67]. Crystal planes of even higher order have been observed [68]. If twinning due to the appearance of stacking faults occurs during nucleation, anisotropic shapes such as tabular crystals will be obtained (see Fig. 1) [69–71].

Silver iodide is never used alone in photographic materials, but always in mixed crystals with silver bromide. Silver iodide exhibits trimorphism: below 147 °C, it crystallizes either as fcc γ-AgI or as hexagonal β-AgI, depending on the growth conditions. A phase transition to body-centered cubed (bcc) α-AgI occurs above 147 °C.

Temperature-dependent lattice vibrations give rise to point defects of the Frenkel type in AgBr and AgCl. Some of the silver ions are displaced from their lattice positions to form interstitial silver ions (Ag_i^+) and silver ion vacancies (Ag_v^-), both of which are mobile. The presence of Ag_i^+ is one of the essentials for the photographic process. The concentration of these two charge carriers in silver halide microcrystals is much higher than the equilibrium value in the bulk silver halide. They are also not uniformly distributed in the small crystals. There is an excess of interstitials near the surface, offset by excess vacancies in the surface. Adsorption effects or doping of the crystals with, for example, multivalent ions can further change the distribution of the Frenkel defects [72], [73].

2.1.3. Interaction with Light

The absorption of a photon of sufficiently high energy (> 2.6 eV) liberates an electron from a halide ion and the electron is promoted from the valence to the conduction band (→ Semiconductors). During its lifetime, the photoelectron thus created (Fig. 2 A) has a mobility of ca. $50\,\mathrm{cm^2\,V^{-1}\,s^{-1}}$. After losing an electron, the halide ion is converted to a neutral halogen atom. The excess unbalanced charges of the surrounding lattice silver ions induce a positive charge at the site of the halogen atom; the resulting positive hole h^+ is mobile by virtue of electron exchange with adjacent halide ions.

$$\mathrm{Br^-} \xrightarrow{h\nu} \mathrm{e^-} + \mathrm{h^+} \tag{2.2}$$

The hole mobility of $1.7\,\mathrm{cm^2\,V^{-1}\,s^{-1}}$ is, however, much lower than that of the photoelectron.

After this primary electronic step, an ionic process can take place, in which the photoelectron combines with an interstitial silver ion to form a silver atom.

$$Ag_i^+ + e^- \longrightarrow Ag \quad (2.3)$$

After several subsequent absorption events, the successively produced silver atoms can aggregate until a silver cluster of sufficient size – the latent-image speck – has formed. Ideally, every photon absorbed should lead to the formation of one silver atom. Since about four silver atoms would be enough to build up a latent-image speck, a grain should consequently be expected to become developable after the absorption of four light quanta. This requires, however, that loss reactions must not occur, that all silver atoms formed must gather at one site only, and finally that the silver aggregate must be located at the surface and not in the interior of the grain, because the developer reacts only with latent-image specks located at the grain surface.

In practice, these requirements are fulfilled only in part . Loss reactions do occur, e.g., by recombination of photoelectrons and positive holes by the reverse reaction of Equation (2.2). This can happen if a charge carrier is temporarily immobilized at a trap (Fig. 2 C) and a charge carrier of opposite sign approaches it because of, for example, Coulomb forces. A hole may also oxidize a previously formed silver atom or silver aggregate; in either case, the direct or indirect result is the loss of a photoelectron and a decrease in the quantum efficiency of the photographic process. Irreversible removal of holes is therefore of paramount importance.

A more-or-less random fine dispersion of photolytic silver in the silver halide grains, instead of a concentration at one (surface) site, is another possible cause of inefficiency in the photographic process. A considerable increase in speed occurs after doping of the crystal surface with "sensitivity centers" (see Section 3.1.3) such as Ag_2S or $(Au, Ag)_2S$. The increase in speed is accompanied (or, rather, caused) by the capability of such centers to direct latent-image deposition to their site [74].

Silver halides absorb light only in the short-wavelength range. Their intrinsic sensitivity is thus restricted to UV or blue light. It can be extended to the entire visible spectrum and beyond, into the IR, if certain dyes (spectral sensitizers) are adsorbed to the grains (see Section 2.2 and Fig. 2 B). The dye absorbs light and is converted to an excited state. This ultimately leads to the formation of a photoelectron in the conduction band of the silver halide and causes photolytic silver formation just as if an absorption event had taken place in the intrinsic absorption band of the silver halide. From thermodynamic considerations it follows that an energy of ca. 1 eV corresponding to a wavelength of ca. 1200 nm is required to break the Ag–Br bond under standard conditions; this represents the long-wavelength limit of spectral sensitization.

Figure 2. Energy-band diagram of photographic effects
A) Absorption of light ($\Delta E \geq 2.6$ eV) in AgBr with the formation of a photoelectron and a positive hole; B) Absorption of light ($\Delta E' < \Delta E$) in a spectral sensitizer with electron transfer from the excited state to the conduction band of AgBr; C) Recombination of a conduction-band electron with a trapped positive hole; D) Capture of a conduction-band electron by an electron trap; E) Herschel effect: Absorption of light ($1.2\,\text{eV} \leq \Delta E'' < \Delta E$) in a silver cluster leads to its ionization and decay

2.1.4. Interaction with Ionizing Radiation

Ionizing Particles. During passage through matter, ionizing particles continually lose energy along their path (the rare case of direct collisions with atoms is not considered here). The energy loss increases with the charge of the particle and decreases with its velocity. The energy transferred to the material may cause ionization; in the case of silver halides, electrons will be liberated, and these will react with silver interstitial ions in the same way as photoelectrons after light absorption. Special photographic materials (nuclear track materials) with a very high vol-

ume concentration of sensitive grains are used to record the tracks of ionizing particles. Information on the identity and energy of the particles can be derived from the number of developed grains per unit path length and the particle scattering [75].

Figure 3. Characteristic curves (density after development versus exposure)
a) Exposure to high-energy radiation (e.g., γ or X-rays); b) Exposure to light; c) Exposure to light with solarization at high exposure values

High-Energy Photons. High-energy photons such as X- and γ-rays, are rather poorly absorbed by silver halides. If, however, an absorption event occurs, a large amount of energy is transferred. Successive ionization events follow, and many secondary electrons are produced. These may escape from the grain which has absorbed the high-energy photons and render adjacent crystals developable as well. The response of a photographic layer to high-energy radiation therefore differs from the response to light (Fig. 3): to become developable by exposure to *light*, i.e., to form a latent-image speck consisting of several silver atoms, a grain must absorb several photons. The response curve (*characteristic curve*), which relates the optical density after development (or the fraction of developable grains) to the exposure, thus has a threshold below which the exposure is not sufficient to make any grains developable. In contrast, the very first *high-energy photon* absorbed by a grain releases so many electrons that latent-image specks are formed and the grain becomes developable. While the characteristic curve for light exposure is sigmoidal, the corresponding curve for exposure to high-energy photons increases from the origin and displays no threshold.

2.1.5. Theories of Latent-Image Formation

The processes starting with exposure and terminating in latent-image formation are not directly observable in detail. Theories have therefore been devised that attempt to describe the steps involved in the formation of a latent-image speck with the aid of known solid-state data on the silver halides along with certain assumptions. Broadly and chronologically speaking, there are *atomistic theories*, which chiefly focus on reaction pathways (how the process takes place), and theories that try to explain why certain events occur and others do not. The second group of theories treat latent-image formation in the framework of *phase-formation* terminology.

Atomistic Theories. The first approach based on solid-state physics was published in 1938 by Gurney and Mott [76]. They assumed that silver halide crystals contain electron traps that can capture photoelectrons (see Fig. 2 D). The initially uncharged trap thus acquires a negative charge, which attracts an interstitial silver ion. The latter reacts with the trapped electron to form a silver atom, and the trap (T) is reset for the next trapping event:

$$(\mathrm{T}) + \mathrm{e}^- \longrightarrow (\mathrm{T}\cdot\mathrm{e})^- \quad (2.4\,\mathrm{a})$$

$$(\mathrm{T}\cdot\mathrm{e})^- + \mathrm{Ag}_\mathrm{i}^+ \longrightarrow \mathrm{Ag}\,(\mathrm{T}) \quad (2.4\,\mathrm{b})$$

$$\mathrm{Ag}\,(\mathrm{T}) + \mathrm{e}^- \longrightarrow \mathrm{Ag}\,(\mathrm{T}\cdot\mathrm{e})^- \quad (2.4\,\mathrm{c})$$

$$\mathrm{Ag}\,(\mathrm{T}\cdot\mathrm{e})^- + \mathrm{Ag}_\mathrm{i}^+ \longrightarrow \mathrm{Ag}_2\,(\mathrm{T}) \quad (2.4\,\mathrm{d})$$

At a certain size, the growing silver aggregate becomes a latent-image speck. Traps can be point or structural crystal defects, but the most efficient ones are assumed to be the sensitivity centers (Ag_2S, etc.) introduced during chemical sensitization. The original theory has been repeatedly modified [77], [78], and several experimental observations seem to agree well with the concept of traps. Examples are (1) the topographic relationship between the location of the sensitivity centers and the site of latent-image deposition [74] and (2) the decrease in photoelectron lifetime after the incorporation of sensitivity centers by chemical sensitization [79], which can be taken as evidence for faster

electron removal. A closer look at this theory, however, reveals certain undesirable details: (1) The negatively - charged transient species occurring in Equations (2.4 b and 2.4 d) could attract highly mobile positive holes instead of slower silver interstitial ions, with resulting recombination and electron loss (Fig. 2 C). (2) If the sensitivity centers are regarded as traps, then increasing their number could give rise to competition in electron trapping, which could lead to dispersed deposition of silver atoms and growing nuclei, so that more photons would have to be absorbed before one of the nuclei could reach the minimum size of a latent-image cluster. This would result in a waste of photons and hence a loss of sensitivity.

In the *Mitchell model* the initial presence of traps is not assumed [80–82]. Electrons are neither accepted by small silver aggregates (up to Ag_3) nor by sensitivity centers. The latter, however, can absorb positive holes. This has two consequences: eliminating the hole lowers the hazard of recombination, and the transfer of the positive charge of the hole to the sensitivity center favors the reaction of an electron with an interstitial silver ion. Once an Ag_3 has been formed, it adsorbs an interstitial and becomes an Ag_4^+. Because of its positive charge, this concentration speck (and the successively larger ones) is now the first deep electron trap. A silver cluster grows at this site through alternating electron trapping and neutralization by interstitial silver ions.

In these two theoretical models, a charged species appears sooner or later; this species enables the growth of a silver phase through its Coulomb attraction for charge carriers with the opposite charge. In contrast, MALINOWSKI [83] assumes that no charged species occur at all. Photoelectrons immediately combine with interstitial silver ions to form neutral silver atoms, while holes form neutral complexes with silver ion vacancies. Silver atoms and hole complexes are mobile; the hole complexes diffuse to the surface, where they release a halogen atom to the environment, and the silver atoms migrate randomly over the surface until they gather into larger aggregates. This event takes place preferentially at condensation centers; the sensitivity centers can be regarded as playing this role [84]. The Malinowski model is a combination of atomistic and phase-formation models.

Figure 4. Free energy change vs. aggregate size
Curves LI and HI are for low and high exposure intensity, leading to low and high supersaturation. An aggregate of size $q*$ may be sufficient to cause developability; the energies of formation are then represented by the vertical distances from the abscissa to the intersection of the respective curves with the dotted vertical. The energy of formation decreases with increasing supersaturation (increasing exposure intensity) and is further reduced at some foreign condensation centers, such as sensitivity centers

Phase-Formation Concept. Here it is assumed that the formation of silver in the silver halide matrix is not essentially different from other processes in which a new phase forms and grows (e.g., condensation from vapor or nucleation from solution or melt) and can be described in principle by the same formalism. In all these cases, phase formation requires the existence of a supersaturated host phase. In silver halides, the supersaturation is created by exposure, which immediately increases the electron concentration from its extremely low equilibrium level [85] to a very high value.

Silver nuclei will be formed in the supersaturated system as described by Equation (2.3). The activation energy ΔG_r for the formation of a nucleus of size r depends in general on the supersaturation c_s:

$$\Delta G_r = 4\pi r^2\sigma - \frac{4}{3}\pi r^3 \frac{RT}{V_{Ag}} \ln c_s \qquad (2.5)$$

(For an explanation of the remaining symbols and the applicability of such equations to microscopic systems, see the discussion on Eq. 2.1).

The activation energy of silver formation is reduced at sensitivity centers (Fig. 4). The rates of the steps leading to the formation and destruction of silver are proportional to exp $(-\Delta G/kT)$. It then follows that the formation probability for a silver aggregate of given size increases with increasing exposure intensity (or supersaturation) and that, at low exposure intensities, not only does the formation probability decrease but – even worse – the decay probability increases. The decay of silver aggregates results from their increasing tendency to become oxidized by positive holes. This is the reason for the occurrence of low-intensity reciprocity failure, which can be reduced if the holes are eliminated by other means (Fig. 5) [86–88]. The lower activation energies at sensitivity centers lead to preferential and concentrated silver deposition at these sites. This fact explains why sensitivity centers increase the speed and also why latent-image specks are preferentially deposited at these centers.

Figure 5. Reciprocity diagram showing log exposure required to reach a given density after development versus log intensity
Curve (a) exhibits three regions: low-intensity reciprocity failure (LIRF) at the left, where the isodense deviates from the horizontal, the horizontal section in the reciprocity range; and high-intensity reciprocity failure (HIRF) at the right. Addition of a halogen acceptor reduces the extent of LIRF (curve b).

2.1.6. Photographic Effects of Exposure

Exposure (to light) is defined as $I \cdot t$, where I is the intensity (irradiance) and t is time. Exposure is measured in energy per unit area, e.g., J/m^2, $W \cdot s/cm^2$, or lux · t, or less frequently (and in scientific work) in incident or absorbed quanta per unit area or per grain. The latter unit is most significant for describing the performance of photographic systems, though measurement is experimentally difficult. The response after development is the *optical density D*; to a first approximation, this is proportional to the fraction of developed grains. The response curve *(characteristic curve)* is obtained by plotting the density versus log exposure. Generally, three regions can be distinguished. At low exposure, no response is observed. As the exposure increases beyond a threshold value, the number of developed grains increases, finally reaching a saturation value (compare Fig. 3 where, however, the exposure axis is not logarithmic).

Certain deviations from this response behavior are known:

Reciprocity Failure (Schwarzschild Behavior). Reciprocity means that a given total exposure (equal to $I \cdot t$) always leads to the same response, i.e., to the same density, independent of the individual values of I and t. Reciprocity failure occurs when, at extreme values of I or t, the total exposure required to reach a given density is higher than in the reciprocal range. Reciprocity can be illustrated by plotting the exposure that results in a given density versus the intensity (Fig. 5) [89]. Reciprocity is obeyed in the region where the curve (the isodense) runs parallel to the abscissa. Simultaneously changing the intensity by a factor f and the exposure time by a factor $1/f$ does not affect the density value in this region.

At low intensities, an increasingly higher exposure is necessary to obtain the given density (*low-intensity reciprocity failure,* LIRF). LIRF is most commonly attributed to the decay of a nondevelopable predecessor of a latent-image speck before the next arriving photoelectron permits growth to the next larger aggregate. This decay is not, or not to a significant extent, a spontaneous process caused by the intrinsically limited lifetime of very small silver aggregates:

$$Ag_n \longrightarrow Ag_{n-1} + Ag_i^+ + e^- \quad (2.6)$$

Instead, it is initiated by a hole (i.e., a migrating bromine atom):

$$Ag_n + h^+ \longrightarrow Ag_{n-1} + Ag_i^+ + Br_L \quad (2.7)$$

which directly oxidizes a silver atom, reduces the size of the silver cluster by one silver atom, and is converted to a lattice bromide ion (Br_L); or it is caused by a bromine atom which is formed

when a positive hole migrates to the crystal surface:

$$4\,Ag_L + h^+ \longrightarrow 1/2\,Br_2 + Ag_i^+ \quad (2.8)$$

For charge compensation, an adjacent lattice silver ion (Ag_i) is released to the lattice as an interstitial silver ion. Lattice ions, although bearing a charge, appear uncharged with respect to the lattice because of the compensating action of adjacent lattice ions with the opposite charge (e.g., Br_L). The bromine atom liberated according to Equation (2.8) then reacts with a silver aggregate at the surface:

$$Ag_n + 1/2\,Br_2 \longrightarrow Ag_{n-1} + Ag^+ + Br^- \quad (2.9)$$

LIRF can therefore be suppressed by elimination of holes or bromine atoms by adding a halogen acceptor (a compound such as a hydrazine that reacts with bromine) to the layer (Fig. 5 B).

Reciprocity failure at high intensities (HIRF) is attributed to the simultaneous formation of silver aggregates at numerous sites, particularly at sensitivity centers [90]. It therefore occurs chiefly when the grains are doped with sensitivity centers having a high degree of dispersion.

Solarization. At high exposure levels, the characteristic curve sometimes bends downward (Fig. 3 C). This behavior results from the destruction of latent-image specks by photolytically liberated halogen at extended exposure times according to Equation (2.9). Solarization occurs when some of the photoelectrons are consumed by silver formation in the interior of the grains. Photolytic halogen can then appear in excess at the grain surface, leading to the oxidation of previously formed latent-image specks. The phenomenon of solarization is the basis for one kind of *direct positive materials*. These contain sensitivity centers in the grain interior (core – shell grains) [91], [92] and chemically produced silver specks at the grain surface. These prefogged (i.e., prereduced) grains are therefore immediately developed without exposure. After exposure, an increasing number of grains become undevelopable because the initially present silver fog specks are more and more oxidized by photolytic halogen. The developed density thus decreases with increasing exposure; a direct positive image results [93].

Herschel Effect. The density due to exposure or chemical fogging decreases after a postexposure to long-wavelength light. Phenomenologically similar to solarization, this effect is based on a different mechanism: Long-wavelength radiation is absorbed not by the silver halide but by previously formed silver aggregates (Fig. 2 E)

$$Ag_n \xrightarrow{h\nu} Ag_{n-1} + Ag_i^+ + e^- \quad (2.10)$$

This leads to their ionization, the transfer of an electron to the conduction band, the formation of an interstitial silver ion, and a reduction in the size of the silver aggregate, which ultimately disappears after sufficient exposure.

For a more detailed description and a listing of other effects, see [94], [95].

2.2. Spectral Sensitization

2.2.1. Theory [96]

Silver halides are sensitive to ultraviolet and, depending on the halide composition, blue light. The long-wavelength limit of spectral sensitivity lies at ca. 420 nm for AgCl, 470 nm for AgBr, and 520 nm for AgI.

The process of extending the sensitivity to long wavelengths is called "spectral sensitization." It involves the addition of dyes (spectral sensitizers) that adsorb to the silver halide. Various classes of sensitizers absorb in the blue, green, red, and infrared parts of the spectrum.

Essentially all photoconductors, whether organic or inorganic, can be spectrally sensitized. The classes of dyes employed depend on the type of semiconductor and the application.

All the spectral sensitizers used with silver halide materials are polymethine dyes [97] (→ Methine Dyes and Pigments), and of these only the ones with cationic (cyanines) or neutral chromophore systems (merocyanines). Dyes with an anionic chromophore (oxonols) are not suitable because they have the same negative charge on the crystal surface as the silver halide (negatively charged due to adsorption of excess halide ions at the surface) and are thus poorly adsorbed.

The preconditions for good adsorption are a planar structure of the dye molecule and the presence of heteroatoms with lone electron pairs, such as nitrogen, oxygen, sulfur, selenium, and tellurium. Suitable heterocyclic terminal groups are pyrroline, pyridine, oxazole, thiazoline, thiazole, selenazole, tellurazole, 1,3,4-oxadiazole, 1,3,4-thiadiazole, and heterocycles derived from these by annelation. In addition to these basic nuclei, the *merocyanines* have, as a second terminal group, at least one "acidic" heterocycle with an active methylene group. Examples of these heterocycles are thiohydantoin, thiooxazolidone, and rhodanine (2-thioxo-4-thiazolidinone). Polymethine dyes with other heterocyclic terminal groups have been described in the literature, but these have not gained much importance as spectral sensitizers.

The sensitizing dye, when adsorbed to the silver halide, has an absorption maximum ("sensitization maximum") wavelength ca. 30 – 50 nm longer than that of single molecules in the dissolved state. Cyanine dyes with cationic chromophores of planar conformation and hindered rotation of the heterocyclic terminal groups, however, tend to form associations or aggregates [98], whose formation is especially promoted if the dye molecules are adsorbed to surfaces. These aggregates have an absorption spectrum much different from that of the single molecule. The absorption maximum of the aggregate is shifted to either longer or shorter wavelengths relative to that of the single molecule. The *shift toward longer wavelengths* is up to 150 nm. It is accompanied by extremely narrow absorption bands that fall off steeply on the long-wavelength side. The cause of the long-wavelength shift in the absorption maximum is the association of molecules in the aggregate in such a way that the angle between the molecular axis and the aggregate axis is less than 54° (preferentially 30° and 19°) [99]. The absorption maximum is *shifted toward shorter wavelengths* relative to the single-molecule value if the angle between the molecular and aggregate axes is greater than 54°. The maxima shifted to longer wavelengths are called J-maxima; those shifted to shorter wavelengths, H-maxima. Both kinds of aggregate bands are important in spectral sensitization. Dyes with J-maxima are indispensable for the spectral sensitization of color materials because of the steep drop on the long-wavelength side; this is the only way to achieve selective sensitivity to individual spectral regions.

The mechanism of spectral sensitization is explained as follows. The dye is promoted from the ground state S_0 to the excited singlet state S_1 by absorption of a photon. In *negative materials*, electrons are transferred from the S_1 state of the dye to the conduction band of the silver halide, with latent-image formation by reduction. Direct electron transfer with the formation of a cationic semioxidized dye free radical ("dye hole") [100] and coupled transfer with the participation of the anionic semireduced dye free radical [101] are under discussion. Energy transfer by the Förster mechanism (radiationless transfer) is also possible but makes only a minor contribution to spectral sensitization [102]. In *fogged direct positive materials*, electron vacancies are transferred from the S_1 state of the dye to the valence band with oxidation of the silver nuclei and the formation of a positive image. The energy levels of the dye molecular orbitals involved relative to the valence and conduction bands of the silver halide determine whether a spectral sensitizer is suitable for negative materials or direct positive materials [100].

Along with its sensitizing action, every spectral sensitizer has a desensitizing action that is independent of light absorption. The desensitizing effect is governed by the constitution of the dye and its concentration on the crystal surface, the type of silver halide emulsion, and chemical digestion. Differences in desensitization are interpreted as resulting from the energy level of the dye molecular orbitals (electron acceptor action) and the statistical distribution of photoelectrons between the crystal and the dye [101], [103]. Desensitization is measured as the decrease of blue sensitivity (intrinsic sensitivity) of the silver halide emulsion in the presence of the spectral sensitizer.

The term *supersensitization* refers to the increase in sensitivity in the spectral range of a sensitizing dye due to substances having a superadditive action (supersensitizers). These can be sensitizing dyes or colorless compounds. Their effect can result from a variety of causes; one such effect is enhanced quantum efficiency of sensitization [104], [105].

A special case of supersensitization is *potentiation*, in which acid (carboxyl, sulfo, sulfon-

amido) derivatives of thiols, enhance the spectrally sensitized sensitivity [106]. This effect is based on increased adsorption of the sensitizing dye to the silver halide crystal.

2.2.2. Blue Sensitization

Sensitization in the blue range of the spectrum is important for silver halide emulsions that are sensitive only in the ultraviolet or ultraviolet plus short-wavelength blue, such as the silver chloride or silver chloride – bromide emulsions used chiefly for photographic paper materials. Blue sensitizers are also indispensable in the silver bromide – iodide film emulsions.

1

X, Y = O, S, Se

R^1, R^4 = H, CH_3, CH_3O, Cl, C_6H_5

2

R^1 = H, CH_3, Cl,

3

Cyanines. The most important cyanines in photography are those with one methine group and a cationic chromophore (monomethinecyanines), such as **1** and **2**.

This group includes, above all, derivatives of benzothiazole (**1**, X=Y=S) with R^1 and R^4=CH_3, Cl, or CH_3O, which are excellent blue sensitizers with a strong tendency to form a J-maximum at 465 – 475 nm. The naphthothiazole cyanines **2** give J-maxima at 480 – 485 nm [107]. These dyes are especially suitable for all color materials (film and paper). In order to prevent residual coloration after photographic processing, dyes with sulfoalkyl residues on the nitrogen [R^2, R^3=$(CH_2)_nSO_3H$] are preferred for their solubility in water.

Special-purpose silver chloride materials can be sensitized with the benzimidazole monomethine dye **3**, whose sensitization maximum is at 440 nm.

Merocyanines. Simple merocynanines (i.e., merocyanines with a zeromethine chain) from rhodanine (**4**–**7**) and open-chain dimethine merocyanines (**8** or **9**) [108] are suitable for blue sensitization of silver bromide and silver chloride – bromide papers in the 450 – 500 nm region.

4

Hydrophilic groups such as carboxyl or sulfo groups in the R^2 and R^3 substituents prevent residual coloration after processing that is needed for paper materials.

2.2.3. Green Sensitization

The following kinds of materials require sensitizing dyes for the green part of the spectrum (500 – 600 nm):

1) Reprographic materials (e.g., line, continuous tone, masking, and contact screen films)
2) Direct positive films
3) Black-and-white papers with variable gradation (see Section 8.3.1.1)
4) Black-and-white films (e.g., amateur, professional, aerial-survey, and motion-picture films)
5) Medical X-ray films
6) Color films (negative, reversal, motion-picture, duplicating, and internegative films)
7) Color papers (negative, reversal)

In keeping with the many applications, the number of industrially important dyes is also large.

Merocyanines. Suitable merocyanines for the range up to 550 nm include dimethine merocyanines with five-membered heterocyclic rings or benzoxazole as basic residues, and with rhodanine, thiooxazolidone, or thiohydantoin as acidic residues, e.g., **10–12** [109], [110].

10

R^2, R^3 = CH_3, C_2H_5, C_6H_5
R^4 = C_2H_5, $CH_2CH = CH_2$

11

These merocyanines are employed for reprographic materials that are processed in red light. Polycyclic merocyanines (**13**) are also suitable for the same spectral range.

X = CH_2, S Y = O, S

12

R^2 = $(CH_2)_3OSO_3Na$, $(CH_2)_4SO_2NHCOCH_3$
R^3 = CH_3, C_2H_3, C_6H_5
R^4 = CH_2COOH, C_2H_5

13

Cyanines. The most important green sensitizers in the industry are trimethinecyanines with benzoxazole or benzimidazole groups. The first, with 9-ethyl and 5- chloro or 5-phenyl substitution (**14**), are used in all color materials because they tend to produce narrow J-bands at 540 – 550 nm; they are the sole green sensitizers utilized in color papers.

14

R^1, R^4 = Cl, C_6H_5; n, m = 2 – 4
M = Na, K, $(C_2H_5)_3NH$

15

R^2 = CH_3, C_2H_5, $(CH_2)_nSO_3Na$
n = 3, 4

16

$R^1 = CN, COOC_4H_9$
$n = 3, 4$

17

$R^2 = (CH_2)_nSO_3^-$; $n = 3,4$
$R^3 = R^2, (CH_2)_2$–C_6H_4–SO_3^-

18

19

In color films, **14** is combined with benzimidazole trimethinecyanines (**15**, **16** and **17**) sensitizing at longer wavelengths (570 – 580 nm), or with naphthoxazole trimethinecyanines **18** or **19** [111], [112]. In **15**–**17**, substituents that lower the basicity of the benzimidazole are essential in order to control fog. Asymmetric trimethinecyanines **20** with two different heterocyclic bases can also be used as long-wavelength green sensitizers in color films.

20

The 2,2′- cyanines **21** are suitable for black-and-white (B & W) films provided they are combined with supersensitizers [113], [114]. Only then can high sensitization quantum efficiencies be achieved at 575 nm.

21

To improve the color reproduction, special sensitizers for the blue-green portion of the spectrum are used [112]; **22**, for example, gives a sensitization maximum at 520 nm.

22

Green sensitizers **23** are employed for variable-gamma B & W papers (i.e., B & W papers with variable gradation) that can be rendered "extra hard" to "extra soft" by controlling the proportions of blue and green light [115].

23

$R^2 = (CH_2)_nSO_3^-$; $n = 3,4$

Polymethine dyes that can break down existing silver nuclei by oxidation when exposed to light are used for green sensitization of fogged direct-positive emulsions. Electron-accepting cyanines such as indole dyes **24** [116] or quinoxaline derivatives **25** [117] are suitable for the green part of the spectrum.

$R^2, R^3 = CH_3, C_2H_5$

24

25

2.2.4. Red Sensitization

Sensitizers for the red, from 600 to 700 nm, can be classified by application:

1) Color negative and color reversal films, color reversal papers must be selectively sensitized between 600 and ca. 660 nm.
2) Color negative papers have a maximum red sensitivity at or above 700 nm, which is the region containing the absorption maxima of the blue-green imaging dyes in color negative films. Panchromatic B & W papers are sensitized for the same region.
3) In panchromatic B & W films, amateur films sensitized up to 650 nm are distinguished from technical films, which are sensitive up to the limit of the visible spectrum.
4) Films for aerial photography have panchromatic sensitization, especially in the long-wavelength red or the near infrared (to ca. 750 nm), to achieve a better penetration of atmospheric haze.
5) Graphic-arts films (lith films and masking films) and materials for laser exposure (holography, scanning).
6) Direct positive films.

Suitable red sensitizers are trimethine and pentamethinecyanines having benzo- or naphtho-1,3-thiazole, -selenazole, or -tellurazole [118] as basic terminal groups; tetramethine merocyanine dyes, rhodacyanines [119]; and polynuclear merocyanines [120]. The spectral sensitivity distribution needed for a given application can be produced by choosing the substituents in the methine chain and the heterocyclic nuclei. In the annelated benzene rings, substitution is usually restricted to small groups such as methyl, methoxy, cyano, fluoro, and chloro; substitution in the methine chain of trimethinecyanines to methyl or ethyl groups on the center methine group (the "meso," μ, or 9 position). Bulkier substituents impair the sensitizing action.

Cyanines. The most important red sensitizers for the range up to 660 nm are found among the 9-methyl- and 9-ethyltrimethinecyanines with benzothiazole end groups. The 9-methylmethines, such as **26** or its 5,5′-dimethyl derivative **27**, have the following effects on silver bromide – iodide emulsions: they give J-aggregate bands at 620 – 640 nm and simultaneously H-aggregate bands in the green at 520 – 540 nm, and they also produce a single-molecule sensitization band (monomer band) at 580 – 600 nm.

These dyes are excellent for use in panchromatic B & W films.

26 $R^1 = H$; $n = 4$
27 $R^1 = CH_3$; $n = 3$

The 9-ethyltrimethines **28** or **29** are characterized by intense, narrow J-aggregate sensitization bands at ca. 650 nm.

28 $R^1 = Cl$; $n = 3$
29 $R^1 = CH_3$; $n = 4$

30

31

These dyes are employed for color films, especially in combination with cyanines **30** or **31** which have two different basic terminal groups, and sensitize in the short-wavelength red between 605 and 620 nm [112]. Such combinations often result in supersensitization and the formation of "mixed" maxima lying between the aggregate bands of the individual dyes [98], [104].

9-Ethylnaphthothiazole and 9-ethylbenzoselenazole dyes, such as **32** and **33**, can be used for sensitization in the longer-wavelength red (660 – 690 nm) in both B & W and color films. These dyes, in combination with sensitizers for the near infrared such as **34**, are of special interest for aerial-survey films [121].

32

33

$R^2 = C_2H_5$, $(CH_2)_nSO_3Na$; $n = 3,4$

34

Benzothiazole and benzoselenazole pentamethinecyanines impart sensitization maxima between 690 and 720 nm to silver chloride and bromide emulsions. Better photographic sensitivity is attained with pentamethines where the methine chain forms part of a cycloaliphatic ring, such as the cyanines **35** that can be derived from isophorone (3,5,5-trimethyl-2-cyclohexenone) [122].

35

X = S, Se
R^1 = H, CH_3, CH_3O, Cl
$R^2 = (CH_2)_3$, SO_3^-; $n = 0$
$R^2 = C_2H_5$ $n = 1$

The sensitivity of materials utilizing these pentamethines (color negative paper, panchromatic B & W paper) can be further enhanced by supersensitization with optical brighteners [123] or heterocycles substituted with thiol groups [124]. This is an important point because the desensitizing action of pentamethines is greater than that of cyanines with shorter methine chains.

Imidazoquinoxaline dyes (**36**) are used as red sensitizers for fogged direct positive emulsions [125].

36

Merocyanines. Tetramethine merocyanines were important red sensitizers in color papers for a long time. Dyes such as **37** are currently being used only for color print films [126].

37

Polycyclic Polymethines. Trinuclear merocyanines have been described as red sensitizers, especially **38** for lith emulsions [127] and **39** for thermally developable materials [128].

38

39

Tricyclic allopolar-isomeric cyanines (i.e., cyanines with mero- and cyanine structure) such as **40** are of some value as supersensitizers, chiefly in the red spectral range [129], [130].

40

41

42

2.2.5. Infrared Sensitization

Hepta-, nona-, and undecamethinecyanines are employed for spectral sensitization above 700 nm (to over 1 µm). The infrared sensitivity can be enhanced by incorporating cycloalkenyl residues in the methine chain, e.g., in **41** [131] and **42** [132], or by the use of supersensitizing combinations [133]. Polymethine dyes with longer methine chains are not suitable as sensitizers, since they are unstable and tend to fog (see above).

2.2.6. Application Technology

Sensitizing dyes can be added to the photographic emulsion in various forms:

1) Solution in organic solvents or in water, with wetting agents if appropriate [134]
2) Dispersion obtained by wet grinding in the presence of wetting agents and grinding aids [135]
3) Emulsion prepared by dissolving a high concentration of the dye in a suitable solvent and emulsifying in water with emulsifiers [136]

Organic solvents used include

1) Low-boiling solvents such as methanol, ethanol, or acetone. These are completely removed in the drying operation after emulsion coating.
2) High-boiling solvents with a high solvent power for polymethine dyes and a low toxicity, such as glycols or glycol ethers (e.g., phenoxyethanol).

Dyes can be added at various stages during emulsion making and the photographic properties are influenced by the stage of addition. For example, introducing the dyes at a high temperature promotes epitaxial adsorption to the silver halide crystals with formation of certain absorption bands.

The optimal quantity of dye added depends on the intended application, the size of the emulsion grain, and the molecular structure of the dye. Fine-grained emulsions require a higher concentration per mole of silver than coarse-grained ones. The dye concentration at the crystal surface required for maximum sensitivity is far less than a monomolecular layer. At higher coverages, desensitization takes place (concentration desensitization). This effect is more pronounced the longer the methine chain in the dye. Infrared sensitizers must therefore be employed at especially low concentrations.

In addition to the spectral sensitivity needed for the material in question, a sensitizing dye must meet many other requirements. As much as possible of the dye added to the silver halide emulsion must be adsorbed to the crystal surfaces, and other additives, such as dye couplers, surfactants, stabilizers, antifoggants must not interfere with this adsorption. Sensitometric properties such as sensitivity, gradation, and fog must not be impaired in storage. The sensitizing dyes in multilayer color photographic materials must not diffuse into adjacent layers (This tendency is especially marked in warm, humid climates). After processing, as little residual sensitizer color as possible should remain in the material; i.e., the dyes must be largely washed out of the layers or bleached in the processing baths. For environmental reasons, application of organic solvents, should be largely dispensed with when adding the dyes to the molten emulsion.

Some of these requirements can be satisfied only partly, or at the cost of other problems. Dyes that are well adsorbed to the silver halide crystal and have a low diffusibility, for example, are difficult to dissolve and tend to leave residual coloration. These include cationic cyanines and merocyanines with benzoxazoles, benzothiazoles, benzoselenazoles, and their higher annelated analogues. The introduction of hydrophilic groups such as carboxyalkyl or sulfoalkyl on the nitrogen lowers the residual coloration, and also improves the solubility if the molecule is present as the anion; however, adsorption of the dye to the silver halide is impaired, and the danger of desorption due to other additives is increased. The ranking of parameters in relation to the material gives rise to the molecular design of a great variety of spectral sensitizers.

2.3. Theory of Development [109], [114]

The photographic (primary) process is not favored over other photochemical processes in terms of quantum efficiency; the maximum quantum efficiency φ of the primary process is always ≤ 1 (see Section 2.1). It is the intensification of the photochemical transformation in the silver halide grains by photographic development that lends the photographic process its high sensitivity to light and makes silver halide photography so superior to all other known photochemical processes. Depending on size a grain (silver halide crystals) of a photographic emulsion contains ca. $10^7 - 10^8$ silver ions and the same quantity of halide ions. For the most sensitive grains, the absorption of about four light quanta [137] is enough to make the entire grain developable. The amplification factor of photographic development is thus ca. 10^7.

When a photographic material is developed, those silver halide crystals bearing a latent-image center Ag_n are reduced to metallic silver by a reducing agent (developer). The latent-image centers have a catalytic action:

$$AgBr + Red^- \xrightarrow{Ag_n} Ag + Br^- + Ox$$

where Red^- is the developing agent (generally present as anion in the alkaline developing solution) and Ox is its oxidized form.

Photographic development is thus based on a kinetic effect. Because of the catalytic action of the latent-image centers, photographic developer solutions (see Section 4.3.2) reduce exposed silver halide grains to silver several orders of magnitude faster than unexposed grains, but after a (sufficiently) long time all the grains are developed, even those that not exposed.

2.3.1. Principle Types of Development

There are two distinct development mechanisms; although they occur in practice only as limiting cases, usually a mixture of both mechanisms is found:

Figure 6. Reactions in physical (A) and chemical (B) development [142]

Physical Development. In physical development [138–141], both silver ions and developing agent from the solution react at the surface of the nuclei. In addition to the nuclei provided by the latent image there are also fog nuclei, whose development leads to the unwanted precipitation of silver at unexposed sites, and metal or metal chalcogenide nuclei deliberately added to the emulsion, for example in the silver halide diffusion process (see Section 4.4).

Two kinds of physical development exist:

Postfixation Physical Development (Fig. 6A). Here, the silver halide is first completely dissolved by complexing agents (see Section 4.3.3.2) and removed from the emulsion layer by washing. The "fixed-out" layer is then treated in a bath consisting of the developer solution and

added silver salt or silver complex. In this process silver formed by reduction is preferentially deposited on the centers formed by exposure (latent image), which are still present in the emulsion layer.

Prefixation Physical Development. Complexing agents are added to the developer solution so that dissolution of the silver halide grain and precipitation of silver at the nuclei in the unfixed layer take place at the same time.

In physical development the silver is precipitated in compact form with high luster and litte covering power [142].

Figure 7. Chemical development
A) Normal case (low silver ion concentration in solution) [144]; B) Ideal case (high silver ion concentration in solution) [148]

Chemical Development. In chemical development (Fig. 6 B), the nucleus is in contact with the surface of the silver halide grain during development. As in physical development, the developing agent is oxidizing at the nucleus – solution interface, but because there is no dissolved silver halide, no silver ions from the solution can be reduced at this interface. Instead, reduction of silver ions occurs at the interface between the nucleus and the silver halide grain [143], [144]. The nucleus grows by silver deposition at this interface; the silver advances into the solution in filamentary form.

In the *normal case* (Fig. 7 A), a quantity of halide ion equivalent to that of deposited silver passes from the surface of the silver halide grain into the solution. Initially, etch pits result on the grain surface; the silver halide grain is completely dissolved in later stages of development. Electron micrographs reveal a jumble of silver filaments and bands; the original grain shape can no longer be perceived. The tangled filaments absorb nearly all the incident light; so little is reflected that the developed silver appears deep black. This deep black form of the developed silver is generally referred to as "Mohr form" after its discoverer [142].

In the *ideal case* (Fig. 7 B) [145], when the concentration of free silver ion in the solution is kept very high by addition of silver salts, the silver ions reduced at the silver nucleus – silver halide interface and thus removed from the grain are quickly replaced by ions from the solution crossing the silver halide – solution interface. The grain is then not dissolved during chemical development, and the mass of silver filaments can be several times as large as that of the silver halide initially present in the grain (see Fig. 8). By a combination of this development technique with a preceding "decoration" (size enlargement by physical predevelopment) of the latent-image specks, it can be shown that the filaments grow out of the AgBr surface like hairs, because the enlarged latent-image specks are found at the tips of the silver filaments.

Figure 8. Silver bromide crystals after ideal chemical development [148]

Most developers now in use predominantly employ chemical development. But the presence of sulfite, which is commonly added to the de-

veloper as an antioxidant (see Section 4.3.2), causes a certain amount of dissolution of the silver halide (especially with slow-acting developing agents) and thus effects some physical development before fixing [146], [147]. Table 1 lists the principal types of development and the conditions under which they are employed.

Figure 9. Dependence of standard redox potential of some developer compounds on pH

2.3.2. Development as an Electrochemical Redox Process

Photographic development can best be described as an electrochemical redox process, in which the latent-image center simultaneously acts as anode and cathode [139–141], [148–152].

At the boundary between the silver nucleus (or silver filament) and the developer solution, the developing agent (Red^-) transfers electrons (e^-) to the silver nucleus and is thereby oxidized:

$$Red^- \longrightarrow Ox + e^- \text{ (anode process)}$$

The excess electrons thus arriving at the silver nucleus are accepted by arriving Ag^+ ions:

$$Ag^+ + e^- \longrightarrow Ag \text{ (cathode process)}$$

In physical development, these silver ions stem from the solution phase; in chemical development, they are interstitial silver ions of the silver halide crystals (see Sections 2.1.2 and 2.3.1).

For thermodynamic reasons the redox potential of the developer (U_{redox}, corresponding to the anode process) must be more negative than the Ag^+/Ag potential ($U_{Ag^+/Ag}$) of the cathode process, which depends on the halide concentration via the solubility product of the silver halide.

The electrochemical potential difference

$$\Delta U = \left(U_{Ag^+/Ag} - U_{Redox}\right) > 0$$

is the driving force of photographic development.

The potentials can be determined with the Nernst equation:

$$U_{Redox} = U^0_{Redox} + \frac{RT}{nF} \ln \frac{[Ox]}{[Red^-]}$$

(anode process)

$$U_{Ag^+/Ag} = U^0_{Ag^+/Ag} + \frac{RT}{nF} \ln [Ag^+]$$

(cathode process)

and

$$U_{Ag^+/Ag} = U^0_{Ag^+/Ag} + \frac{RT}{nF} \ln [Ag^+]$$

(cathode process)

Here U_{redox} is the electrode potential of the developer solution, U^0_{redox} is the standard potential of the developing agent, $U_{Ag^+/Ag}$ is the potential of silver in the solution, and $U^0_{Ag^+/Ag}$ is the standard potential of silver.

For the very small silver nuclei of the latent image, the Ag^+/Ag equilibrium potential $U_{Ag^+/Ag}$ does not correspond to that of a massive silver electrode. Because of the large interfacial energy of these small silver particles, the equilibrium potential of the cathode process shifts toward negative values with decreasing particle size [153–155]. Tests with reversible redox systems have led to quantitative relations between this shift in $U_{Ag^+/Ag}$ and the Ag particle size [156–158]. Therefore with more negative values of U_{redox} (at given $U_{Ag^+/Ag}$) not only the rate of silver deposition at the development nuclei increases, but also smaller silver nuclei are developed, so that the light sensitivity of the photographic system increases.

Table 1. Types of photographic development

Process	Addition of silver halide solvent	Addition of silver ion or silver complexes	Anodic and cathodic potential (relative to the Ag^+/Ag-potential of the emulsion layer)
Postfixation, physical development	before development	Ag^+-complex added to developer	positive
Prefixation, physical development	during development	Ag^+-complex formed by dissolution of grain during development	negative
Normal, chemical development	none	none	negative
Ideal, chemical development	none	Ag^+-ions (high concentration) added to developer	positive

As soon, however, as the electrochemical potential difference of the developer system passes a critical value of $\Delta U' \approx 200$ mV, the internal energy of this redox-system is high enough to supply the energy necessary for nucleation so that new silver nuclei can appear. Spontaneous nucleation then begins, and the photographic system becomes spontaneously fogged.

The relation between the development activity of organic developing agents and the pH can be simply derived from the pH dependence of the developer's redox potential. This pH dependence is due to the removal of protons from the developer molecules in alkaline solution. Because of the greater number of single electron pairs, the anions of organic developing agents present at high pH are stronger reductants than the protonized developer molecules present at low pH values [159], [160]. Figure 9 shows the pH dependence of the standard redox potentials of several developing agents.

The pH dependence of the activity of a developer is not always determined solely by its transformation from one ionic form to another. Studies on *p*-phenylenediamines, for example, show that their development activities vary strongly in the pH range from 7 to 13, although no p*K* values exist in this range [161]. This is explained by the pH dependent inhibiting action of the oxidation products [162].

2.3.3. Development as an Electrode Process

2.3.3.1. Models of Single-Grain Development Kinetics

Treating the development process in terms of an electrode process and dividing it into partial processes has led to predictions about the growth kinetics of silver on the single grain [148–152]. The results obtained have been compared with determinations of the volumes of the developed silver particles from electron micrographs [163], [164].

Physical Development. In physical development, anodic and cathodic transfer takes place at the silver nucleus – developer solution interface. The application of electrode theory has given a relation between cathodic and anodic current – voltage curves, the working potential, and the kinetics of physical development (see Fig. 10).

In a model the nucleus can be regarded as a silver electrode connected by an insulated wire to a counterelectrode immersed into the solution. If the solution contains silver ions only, the electrochemical potential at the silver nucleus takes the value $U_{Ag^+/Ag}$ predicted by the Nernst equation and no current flows. If an external emf imposes a more negative potential on the nucleus, an Ag^+ ion current flows to the silver electrode, where the ions are neutralized in accordance with the cathodic current – voltage curve (c in Fig. 10) and silver is deposited.

If the silver nucleus in the same configuration is brought into contact with a solution that contains only the redox system of the developer, the anodic current – voltage curve (a) can be derived in a similar way. The magnitude of the current corresponds to anodic oxidation of developer molecules (Red^-).

In physical development the silver nucleus is in contact with a solution which contains both reaction partners. With respect to silver deposition, it acts as a cathode and must establish the potential $U_{Ag^+/Ag}$ if no external emf is imposed. With respect to the oxidation of the developing agent (Red^-), the silver nucleus acts as an anode and

tends to have the potential U_{redox}. In reality, a steady-state working potential $U*$ comes about; this is the abscissa of the intersection $P*$ of the two current – voltage curves. The corresponding current $i*$ is directly proportional to the silver deposition rate and the formation rate of the developer oxidation product ($dn/dt = i*/e$, where e is the electron charge). The potential difference $U_{\mathrm{Ag^+/Ag}} - U*$ is the driving force of the cathode process, while $U* - U_{\mathrm{redox}}$ is that of the anode process.

The slope of the current – voltage curves depends on the size of the nucleus, among other factors. For diffusion-limited physical development, $dn/dt \sim r$, where r is the radius of the nucleus; since $r \sim n^{1/3}$, the time dependence is $n \sim t^{2/3}$. If the rate is limited by a reaction at the surface of the nucleus (e.g., electron transfer from the developer molecule to the silver nucleus, dehydration of silver ion, dissociation of the Ag^+ complex), $dn/dt \sim r^2$; hence the time dependence for transfer-limited physical development of a silver nucleus is $n \sim t^3$ ([139–141]).

Figure 10. Cathodic (c) and anodic (a) current – voltage curves $i = f(U)$ for physical development [142]

Chemical Development. In chemical development, the outside of the silver center toward the developer acts as the anode (silver – solution interface). In the cathodic process, silver ions of the silver halide crystal lattice are transported through the crystal, via the interstitial lattice, to the nucleus – silver halide interface, where they are reduced to silver (see Fig. 11).

In the anode process the limiting step can be, e.g., the electron transfer or the diffusion of developing agents to the electrode (or the diffusion of developer oxidation product from the electrode); in the cathode process, it can be the electron transfer or the diffusion of silver ions in the crystal, the escape of halide from the crystal, or adsorption. In addition, the anode area increases in proportion to the silver deposition during filament growth, while the cathode area remains constant. It can be derived from this model that filament growth should follow an exponential function [165]. Kinematic investigations of development on specially grown large, tabular AgBr grains have shown, however, that the rate of silver filament growth is very often rather constant over time (see, e.g., [166]) after an induction period (see below). This is explained by the assumption that the constant inward migration of Ag^+ ions through the AgBr crystal to the Ag filament/AgBr crystal contact (i.e., the cathode process) becomes the rate-limiting step [139–141].

Regarding the proportion of physical and chemical components in development as a function of development conditions, see [167].

Figure 11. Electrochemical model of chemical development [152]
A=anode; C=cathode; E=electron; Red=reduced form of developer; Ox=oxidized form of developer

Induction Periods. Whether the development of a single grain begins immediately or after an induction or "latency" period depends on the developer and the process conditions. This behavior is accounted for by prior reactions that must first overcome a potential barrier created by the ionic charge of the developing agent and the electrostatic field around the silver halide grain [168]. The silver halide crystal in the emulsion layer is generally surrounded by a shell of

Br^- ions generated during manufacture. Therefore, the potential barrier becomes higher as the negative charge of the active developing agent Red^- increases. Another explanation for the occurrence of an induction period is the transition from spherical to filamentary growth of the nucleus [169]. Induction periods after short exposure to light with high intensity, whereby many very small nuclei are generated, are generally longer than after long exposure to light with low intensity, which produces fewer but larger latent-image centers (see Section 2.1.5). This implies that differences in the induction period can also be due to differences in the size or size distribution of the latent-image centers.

2.3.3.2. Development Kinetics of Emulsions

From the photographic standpoint, development rate of emulsions is defined as

1) The growth rate of the optical density D at a given exposure or
2) The rate of increase of gradation (i.e., of γ; see Section 6.1).

The first definition is more useful in basic studies of development kinetics in the emulsion. The rate of increase of optical density is described according to Hurter and Driffield (see e.g., [170]):

$$\frac{dD}{dt} = K \cdot (D_\infty - D)$$

where D is the optical density at time t, D_∞ that after infinitely long development, t is the development time, and K is a rate constant given by

$$K = k \cdot [\mathrm{RedH}]^a \cdot [\mathrm{OH}^-]^\beta$$

where k is another rate constant and a and β are exponents with values between 0 and 1.

In attempts to work out a detailed description of the development mechanism, the quantities k, a, and β have been determined under widely varying development conditions (cf., e.g., [168], [171], [172].

Mathematical models have also been devised for the development kinetics of emulsions [173–176].

The principal factors governing the development kinetics of emulsion layers are

1) The nature and concentration of the developing agent
2) The development temperature
3) The pH
4) The nature and concentration of special compounds in the developing solution (sulfite, halide, accelerators, restrainers, developer oxidation products)
5) The nature and properties of the silver halide grains in the emulsion (halide composition, grain size, packing density)
6) Exposure conditions (high- or low-intensity, etc.)
7) The properties of the layer, such as thickness, swelling, hardening, and contents of silver halide, color coupler, plastics etc.

Any emulsion layer is composed of very many silver halide grains. Two limiting cases can therefore be described (see Fig. 12):

Figure 12. Increase in optical density D of an emulsion versus time, for (A) simultaneous development of all grains; (B) fast development of individual grains differing in induction period
D_{tot}=total density of the layer, D_G=single-grain density contribution, t_g=development time of the individual grain, L denotes several induction periods

1) Each grain is developed immediately at the start of development; there is *no induction period*. The time dependence of the process for this collective of grains is essentially determined by the (average) time dependence of the development of the single grains.
2) Any one grain is completely developed very rapidly, but the individual grains have *widely differing induction periods*. the development kinetics of the layer is then essentially governed by the statistical distribution of these induction periods.

Figure 13. Rate of overall development versus proportion of the developing agents hydroquinone and Phenidone, for a constant total concentration of 0.01 M [179]
Solid lines=expected curves (additive behavior); Dashed curves=experimental curves

2.3.4. Development Effects

2.3.4.1. Superadditivity

A mixture of two developing agents exhibits superadditivity if a measured quantity (e.g., development rate, or optical density after a given exposure and development time) of the mixture has a higher value than that would be obtained as the sum of these quantities for the unmixed substances times their molar fractions.

An example is given in Figure 13. The tie lines between the development rates measured with the unmixed (100 %) developing agents represent the expected "normal" values for mixtures. Any values lying above these tie lines are superadditive [177–179]. If developer mixtures show superadditivity, they generally do so in both chemical and physical development [180].

The following explanations have been proposed for the mechanism of superadditivity:

The induction period of developer ions B, bearing a highly negative charge (e.g., hydroquinone, pyrogallol, catechol, or ascorbic acid in alkaline solution) is shortened by the less negatively charged or neutral developer molecules A because these are less sensitive to the negative charge barriers around the silver halide grain (see Section 2.3.3.1). In this way the development rate is enhanced [181], [182].

Developing agent B, which acts more slowly and/or with an induction period, regenerates faster developing agent A. For example, a slow electron transfer from the more active reducing agent B to the silver can be accelerated by the weaker reducing agent A (i.e., A acts as a redox catalyst) [183–185]. For example in the case of a superadditive mixture of hydroquinone and Phenidone, the reaction between the hydroquinone anion and the Phenidone radical cation is assumed to be the rate-limiting step [185].

In the superadditive hydroquinone/Phenidone mixture at pH$\geq$10.5, the Phenidone eventually also displaces adsorbed SO_3^{2-} ions that may block electron transfer from hydroquinone to Ag [185].

2.3.4.2. Adjacency Effects

The structure of a photographic image can be heavily influenced by adjacency effects [186], [187]. These effects, also called Eberhard effects after their discoverer, are particularly marked when

1) The developer concentration is low
2) Only a limited quantity of developer is available (e.g., in the development of instant pictures with viscous developers; see Section 4.4)
3) The developer solution has little pH buffering capacity

In color photography, development inhibitor releasing (DIR) couplers (see Section 5.2.2.5) are used to produce very strong adjacency effects in the color layers. Horizontal (edge) effects improve image sharpness, vertical (interimage) effects improve color quality.

Localized diffusion fluxes and restricted transport of developing agent and (development-inhibiting) byproducts are necessary for these adjacency effects (see Fig. 14).

Figure 14. Horizontal adjacency effect (edge effect) due to developer depletion and inhibiting byproducts [19, p. 609] For explanation see text.

If the emulsion is exposed to an image having a detail with an edge (Fig. 14 A), then during development the developer becomes depleted in the exposed region of the layer, while halide or other development-inhibiting substances are produced there. As a result, development is retarded in this region.

Near the edge of the exposed region, however, fresh developer diffuses in from the adjacent unexposed part of the layer while inhibiting byproducts diffuse out. Mass transport between the layer and the developer solution is too slow to maintain the same concentrations of developer and inhibiting compounds in this edge region as in a homogeneous (exposed or unexposed) region (Fig. 14 B and C). The result is a higher optical density in the layer inside the exposed region next to the edge and a lower (fog) density in the unexposed region next to the edge. The contrast in optical density is thus enhanced on a microscopic scale; as a rule, this improves the sharpness of the image.

At the sprocket holes, however, the horizontal adjacency effect can have a very detrimental result. Fresh developer diffuses laterally into the photographic layer and can produce density streaks; these may generate interference frequencies in motion-picture films, especially in those with optical sound tracks.

Vigorous agitation of the developer solution promotes mass transport between the emulsion and the solution and thus weakens the adjacency effects. Adjacency effects can be quantitatively described by the line spread function [188], [189].

2.3.4.3. Direct Positive Development

In certain emulsions the latent-image centers are formed only inside the grains on exposure. These emulsions can be developed into direct positive images with special developer solutions [190], [191]. Such grains can be produced, for example, if after chemical digestion the digestion nuclei generated at the grain surface are "buried" in the grain by precipitation of more silver halide (see, e.g., Section 2.1.6).

The developer solutions used for this process contain, along with the developing agent, very small amounts of an especially strong reducing agent (e.g., a hydrazide) as a fogging agent. This reducing agent injects electrons from the developer solution into the silver halide grain [192]. In those grains where internal latent-image centers have been formed during exposure, these centers "draw" the injected electrons into the bulk of the grain, so that no fog nuclei (development centers) can arise on the surfaces of these exposed silver halide grains. As a result, only the grains that were not exposed are developed in such a fogging developer. This principle is utilized in instant color photography.

2.4. Photographic Properties and Their Control

Photographic materials based on silver halides are used in all areas of life. In addition to the broad assortment of B & W and color films and papers for amateur use, a wealth of special-purpose photographic materials exist, such as motion-picture films, graphic-arts films for use in the printing trades, X-ray films for use in medical diagnostic and materials testing, microfilm for archival use, and special films for scientific applications, e.g., in astronomy, holography, and nuclear research. All these materials have photographic emulsions as the light-sensitive component. This term "emulsion," which is physically incorrect, refers to the system of silver halide microcrystals (emulsion grains) in a matrix of a protective colloid, usually a dried and hardened gelatin layer (→ Gelatin).

All color photographic materials, and many B & W ones, have multiple emulsion layers that often contain mixtures of several emulsions, and in general any one emulsion can perform only the functions specific to it in a particular layer. The reasons for this limitation are the sensitometric requirements of the product, which differ sharply from one application to another; the complex interplay of the individual components in a photographic material; and the different developing and processing techniques employed with the several product groups. Accordingly, any photographic emulsion must be optimized for its special function, though compromises must always be made because certain properties vary contrarily. The modes of controlling the photographic properties include methods used in emulsion making and practices employed in the layer-by-layer construction of photographic materials with painstaking selection of all components.

The following sections mainly deal with the effect of the emulsion and to a first approximation the properties of the single grains are examined as representative of the emulsion. Virtually every innovation in emulsions is conceived of at the single-grain level and then extended to the greatest possible number of grains at once. There has been a trend toward more and more uniform emulsion grains in photographic materials for some years. In turn, modern physical analytical methods (see Section 3.1.4.3) on individual emulsion crystals have gained importance. In reality, any photographic image involves very many emulsion grains that react; for example, an ordinary ASA 400 color film has on the order of $10^9 - 10^{10}$ grains per square centimeter.

Figure 15. Theoretical sensitivity (quantum threshold 4 photons) as a function of grain size and shape [3]
Dashed curves show sensitivities attained in current practice

2.4.1. Sensitivity, Granularity, Sharpness

The sensitivity or speed of emulsion depends, above all, on the grain size. The larger the grains, the greater the number of incident photons per grain at a given exposure, and thus the higher the probability that a latent-image center will be formed. To obtain a numerical correlation between sensitivity and grain size, the intrinsic sensitivity of the emulsion grains must be distinguished from the spectral sensitivity imparted by dyes on the grain surface. The intrinsic sensitivity is proportional to the grain volume V; the spectral sensitivity, depending on absorption in the dye layer adhering to the grain, is proportional to the grain area S.

Figure 15 shows that these linear functions are valid only up to some limiting values; beyond these levels (dashed curves), the sensitivity increases more slowly and eventually decreases because of loss reactions in latent-image formation. If the sensitivity is enhanced by enlarge-

ment of the emulsion crystals (when enlargement is possible at all), the granularity of the developed silver in B & W films or the structure of the dye clouds in color films becomes coarser so that the image quality is impaired, especially in an enlarged print or transparency. In general, therefore, the desired sensitivity should be achieved with the smallest possible crystals, and the crystals must have optimal geometry. The emulsion grains for the blue part of the spectrum may be compact, while those to be sensitized for the green and red should ideally have a tabular shape. If the tabular grains are sufficiently thin (for instance, 0.2 μm in Fig. 15), they have a large area *S* but a relatively small volume.

Even with the minimum grain volume for a given sensitivity, the granularity can be substantially improved if development is retarded or even stopped before the entire grain is developed. This can be done with DIR couplers (see page 79); i.e., substances that react with part of the developer oxidation product and release an inhibitor. save

The halide composition is also important in the sensitivity – granularity relationship. The best results are achieved with AgBr – AgI mixed crystals with an iodide content of 2 – 15 %. The iodide should advantageously be incorporated in an interior zone of the grain to increase the sensitivity and to achieve proper interaction with the DIR coupler. High iodide concentrations at the crystal surface should be avoided as much as possible, because otherwise development is retarded from the very beginning and the sensitivity attained will not be high.

The sensitivity of an emulsion is greatly enhanced by chemical sensitization or ripening, in which aggregates of Ag_2S, or AgAuS are formed at the grain surface (see Section 2.1.3). The latent image is then formed on relatively few sensitivity specks on the grain surface, whereas in the unripened crystal, it forms preferentially on internal lattice defects and is inaccessible to the developer. The sensitivity can be increased by a factor of ca. 10 – 50 by chemical sensitization.

All measures aimed at increasing the sensitivity – in addition to those mentioned already there are many that are part of the carefully guarded know-how of every manufacturer – can be categorized under one of three basic concepts:

1) Enhanced light absorption (through halide composition, grain shape, dyes)
2) Improved efficiency of latent-image- center formation (through halide configuration, interfaces, doping, digestion)
3) Accelerated development [through emulsion additives such as polyalkylene oxides, development-accelerator releasing (DAR) couplers, halide scavengers]

The emulsion influences not only the sensitivity and granularity, but also the *sharpness* of the photographic layer. Sharpness is decreased first of all by the scattering of light on the individual emulsion grains. On the other hand, scattering increases sensitivity by lengthening the light path inside the emulsion layer and thus increasing the absorption. Scattering is at a maximum at grain sizes of ca. 0.30 μm and decreases in both larger and smaller grains. As a compromise between desired increase in sensitivity and undesired decrease in sharpness, the total amount of emulsion applied is kept as small as possible, and the strongly scattering grain-size fraction of ca. 0.3 μm is omitted, at least from the top layers, in order to hold down the sharpness loss in the layers beneath. Sharpness can also be improved by filter dyes added to the emulsion layer. These absorb in the same range of wavelengths where the emulsion is spectrally sensitized, thus reducing the diffusion halo but simultaneously also the sensitivity. The sharpness of a photographic layer also depends on its thickness. The thicker the layer, the larger the scattering cone (which widens along the light path) or the halo. The production of thin layers requires highly concentrated emulsions (high silver halide concentration, low gelatin content).

2.4.2. Gradation, Development Kinetics, Reciprocity

Gradation. The relationship between grain size and sensitivity implies that the characteristic curve of an emulsion with a broader grain-size distribution will cover a wider range of illuminance, that is, show a lower gradation (see Section 6.1). The grain-size distribution can be controlled over a wide range during emulsion making. Sometimes it is advantageous to synthesize a broad distribution by blending homodisperse emulsions (see Section 3.1.1) of different

grain size. Chemical sensitization always broadens the sensitivity distribution and thereby renders the gradation lower. Thus, even homodisperse emulsions do not have an arbitrarily steep gradation.

A fundamentally different approach to high gradation values is the doping of the emulsion grains with heavy-metal ions such as those of rhodium, cadmium, lead, and bismuth. Doping pushes back the toe of the characteristic curve and produces a steep gradation. For ecological reasons, however, cadmium salts are no longer employed in photographic materials.

Finally, the halide composition of the emulsion crystals affects not only the sensitivity but also the gradation. The gradation becomes lower with increasing iodide content. This is due to a broader sensitivity distribution and a slower rate of development.

Kinetics of Development. It is the rate of development, however, that becomes more and more important as processing speeds rise. This holds especially for photographic papers, in which fast-developing silver chloride emulsions are increasingly used.

Color film emulsions, in contrast, must not develop too rapidly; instead, their development must be retardable, for example by inhibitors released during development (see Section 5.2.2.3). In this way, not only can the granularity be improved, but edge and interimage effects that are important for image quality can also be attained. In general, the development kinetics of emulsions in color materials (especially color films) must be precisely matched – both to one another and with respect to the interplay with dye couplers and DIR couplers.

Reciprocity. The two kinds of reciprocity failure discussed in Section 2.1.6, LIRF and HIRF, can seriously impair the image quality. Since the individual grain-size fractions often differ in reciprocity, these failures manifest themselves not only in a loss of sensitivity but even more in gradation changes. Since reciprocity failure cannot be eliminated entirely, the changes in the color layers must be at least of the same kind, so that color imbalances will not occur. This sort of matching is essentially done through the emulsions.

Besides the addition of halogen acceptors, LIRF can most effectively be controlled by doping the emulsion grains with Ir, Ag_2, or Ag_2S nuclei. To prevent HIRF, chemical sensitization must be done in such a way as to ensure that the sensitivity specks are formed only at a few sites on the grain surface (see Section 2.1.6).

2.4.3. Stabilization

All photographic materials are chemically stabilized so that their sensitometric properties will change as little as possible during long storage, even in the presence of heat and high atmospheric humidity. The properties affected by such changes, usually include sensitivity, gradation, and fog; most commonly, sensitivity and gradation decrease and fog increases. These instabilities are caused by chemical reactions that continue inside the silver halide layers or by outside influences (e.g., atmospheric oxygen, humidity, cosmic and radioactive rays) that come into play during storage.

Important factors controlling the stability of an emulsion are the pH and pAg (negative logarithm of the concentration of silver ion). Suitable pH and pAg values are different for various photographic materials. Even so, an optimal choice of these two values will not alone result in adequate photographic stability. Additives called "stabilizers" are also necessary. These act chiefly by adsorbing to the silver halide crystals and forming sparingly soluble silver salts. The exact mechanism of stabilization is not known.

Typical classes of substances and examples of the associated stabilizers include the following:

1) Azaindenes or indolizines: 4-hydroxy-6-methyl-1,3,3a,7-tetraazaindene

2) Imidazoles: 5-nitrobenzimidazole

3) Triazoles: 1H-benzotriazole

4) Tetrazoles: 2-mercapto-1-phenyltetrazole

5) Thiazoles: 2-mercaptobenzothiazole

For a comprehensive bibliography on stabilizers, see [3]. Other compounds of practical value are those that release effective antifogging agents only during development (see Section 5.2.2.3).

Because of their gelatin content, photographic emulsions require bactericidal additives as preservatives. These include phenol, pentachlorophenol, thymol, and *p*-chloro-*m*-cresol. Biocides are usually added to the emulsion after chemical sensitization.

3. Manufacture of Photographic Materials

3.1. Emulsions

[14][15][19][27][31][193][194][195][196][197]

As discussed in Section 2.4, many photographic properties are directly influenced by the silver halide emulsion. The size, shape, and composition of the light-sensitive microcrystals allow a great variety of modifications. Despite this variety, the production of virtually every photographic emulsion can be broken down into three basic steps:

1) **Precipitation and Physical Ripening.** Silver halide crystals are formed in the desired size or size distribution with the desired chemical makeup. This step largely establishes the photographic qualities of the emulsion.
2) **Removal of Soluble Salts.** The soluble salts from precipitation are removed by washing. If coagulation or ultrafiltration is employed, the emulsion can be simultaneously concentrated to a high degree.
3) **Chemical Sensitization.** The emulsion is digested in the presence of special agents at ca. 45 – 65 °C. Sensitivity specks are formed on the surface of the emulsion grains; on subsequent exposure, these will facilitate the formation of latent-image centers. At the same time, this step markedly enhances the sensitivity.

3.1.1. Precipitation and Physical Ripening

To a prepared aqueous gelatin solution (ca. 2 – 5 wt %), aqueous solutions of silver nitrate and an alkali halide are added with vigorous stirring between 30 and 80 °C. Ammonium halides used to be employed frequently but are now avoided for environmental reasons. Because of the relatively low solubility of silver halides, the liquid phase becomes supersaturated as soon as the reactants come together, and silver halide nuclei form. The gelatin acts as a protective colloid and prevents the coagulation of the microcrystals. As precipitation continues, new nuclei can be formed but silver halide can also grow onto the ones already formed. The latter process is favored energetically. The dissolution of small unstable particles and reprecipitation onto larger crystals begins in the first instants of precipitation. This process is known as physical or Ostwald ripening. The driving force for this redissolving process is the increased solubility L_r/L_∞ of small particles which can be calculated with the Gibbs – Thomson equation. A plot of L_r/L_∞ versus particle size is shown in Figure 16 for AgBr. As a result of this increased solubility, the mean particle size of the disperse system increases while the number of particles declines, so that the total surface area and energy also decrease. Coagulation or coalescence processes, in which two or more microcrystals come into contact and grow together, are less important but give the same result. Finally, the process known as recrystallization occurs when crystals differing in halide composition are present. Again, the system tends toward the lower-energy state, in this instance, the formation of mixed crystals. Which of these growth mechanisms dominates (or excludes) all the others during emulsion making depends on the precipitation conditions, which usually vary over time. They include the order and rate of addition and the concentrations of the reactants, as well as the solubility of the silver halides, which depends on

temperature, pH, and complex formation. The nature and concentration of the gelatin can also play a crucial role in precipitation. All these factors imply a great diversity in the emulsion formulas. In view of the complex relationships between emulsion-specific and photographic properties, it is not surprising that the development of new formulations involves not only theoretical but also empirical knowledge. Some significant features of emulsions and emulsion making are described in what follows.

Figure 16. Relative increase in solubility L_r/L_∞ for AgBr in water at 50 °C versus particle size [14]

Single-Jet and Double-Jet Methods. If one reactant is present in the gelatin solution and the other is added, the precipitation scheme is called *single-jet process*. Precipitation is *direct* if the halide is initially in solution or *inverse* if the silver nitrate is. In a *double-jet method*, both reactants are added to the precipitation vessel at the same time. The rates of addition can differ greatly. Feed times commonly range from a few seconds (for some single-jet emulsions) to several hours for double-jet precipitations. The solutions can also be divided into several portions added at intervals. Emulsion making by the single-jet method, but also by some double-jet processes occurs with a high excess of halide ions during precipitation. The halide concentration $[X^-]$ which is related to the silver ion concentration $[Ag^+]$ through the solubility product of the silver halide $[Ag^+] \cdot [X^-] = K_{sp}(AgX)$ strongly influences the solubility of the emulsion grains. This relationship is plotted in Figure 17 for AgBr. The solubility is at a maximum at the equivalence point; as either the Br^- or the Ag^+ concentration increases from this point, it goes through a minimum, and at still greater ion concentrations the solubility rises again because in larger excess either ion can form soluble complexes with the corresponding counterion. In Figure 18 the solubilities of AgCl, AgBr, and AgI are plotted for the preferred working range of halide excess.

Figure 17. Solubility of AgBr in water at 50 °C versus concentrations of bromide and silver ions [14]

Figure 18. Solubilities of silver halides AgX (X=Cl, Br, I) in water at 25 °C versus halide concentration [14]

Photographic emulsions generally do not consist of a single silver halide but of a blend

of halides. The individual salts are precipitated in order of increasing solubility. When a solution of $AgNO_3$ is added to an initial mixture of alkali bromide and iodide, the sparingly soluble pure AgI precipitates first. This process continues until the iodide concentration in the solution has fallen to a value of

$$[I^-] = \frac{K_{sp}\,AgI}{K_{sp}\,AgBr}\,[Br^-]$$

A mixture of AgI and AgBr then precipitates; the ratio of the iodide and bromide concentrations $[I^-]$ and $[Br^-]$ is equal to the ratio of the solubility products. AgBr – AgI emulsions made by the single-jet method therefore have a higher iodide concentration in the interior than in the outer regions of the grain and large grains have a higher iodide content than smaller ones. While silver chloride and silver bromide, both of which crystallize in the fcc lattice, form mixed crystals in all proportions, silver iodide with its hexagonal lattice can be incorporated into AgCl and AgBr only up to some limiting concentration. A miscibility gap exists if the iodide content exceeds ca. 40 mol % in the AgBr – AgI system. The upper limit of miscibility i (in mol %) is a linear function of the temperature ϑ (in °C) [19]:

$$i = 34.5 + 0.165\,(\vartheta - 25)$$

Figure 19. Solubility of silver bromide in aqueous solution versus bromide ion concentration at various temperatures [14]

Acid, Neutral, and Ammoniacal Emulsions. The first two types of emulsions are prepared with silver nitrate present in an acid or neutral solution. Both single-jet and double-jet methods are suitable, preferably a large halide excess is used at a temperature ca. 50 – 80 °C. The solubility of the silver halides increases with rising temperature (Fig. 19).

The solubility products $K_{sp}(AgX)$ as functions of temperature T (in K) can be approximately described as

$$K_{sp}\,(AgCl) = 2 \times 10^{-\frac{3000}{T}}$$
$$K_{sp}\,(AgBr) = 468 \times 10^{-\frac{4470}{T}}$$
$$K_{sp}\,(AgI) = 33 \times 10^{-\frac{5090}{T}}$$

Within certain limits, the grain size and grain-size distribution – in photographic terms, the sensitivity and the gradation – can be controlled through the precipitation temperature alone. Complexing in general, and in particular *complexing with ammonia*, increases the solubility of the silver halides even more than raising the temperature (Fig. 20).

Figure 20. Solubility of silver bromide in aqueous solution at 25 °C versus $[Br^-]$ at various ammonia concentrations

Commonly, concentrated aqueous ammonia solution is added to the silver nitrate solution until the silver hydroxide, which precipitates first, is dissolved as a silver diammine complex $[Ag(NH_3)_2]^+$. The ammonia can also be added together with the halide. The precipitation method in the presence of ammonia is restricted to the sparingly soluble silver halides

AgBr and AgI and blends of these. Silver chloride emulsions cannot be precipitated from ammoniacal solution because the solubility is too high in this setting. Ammoniacal emulsions are prepared at a relatively low temperature during precipitation and physical ripening. Due to the high vapor pressure of ammonia the temperature must generally be kept below 50 °C. After physical ripening, the excess ammonia is neutralized with acid. The ammoniacal precipitation method still finds use in the preparation of coarse-grained X-ray emulsions. This process has the drawback of a relatively high ammonium ion load in the wastewater. Acid and neutral emulsions on the one side and ammoniacal emulsions on the other show characteristic morphological differences. The first, as a rule, show highly anisotropic crystal growth in the form of thin, often sharp-edged, three- or six- cornered tablets; the second exhibit no distinct growth orientation but take on a more and more spherical form in the course of precipitation and physical ripening.

These earlier precipitation methods are characterized by the fact that the crucial parameter for the quality of an emulsion made in these ways is the solubility during the emulsification process. As a rule of thumb, the higher the solubility (which depends on pAg, pH, temperature, and complexing) and the longer the precipitation and Ostwald ripening time, the coarser and more heterodisperse the emulsion becomes. And conversely, the emulsion becomes finer-grained and more homodisperse the lower the solubility and the shorter the precipitation time.

Converted Halide Emulsions. The conversion process was used especially for the production of paper emulsions. It is based on the transformation of more easily soluble silver halide grains to more sparingly soluble ones. Thus, if bromide is added to an AgCl emulsion, most of the halide is converted to an AgBr emulsion and chloride is liberated:

$$\mathrm{AgCl} + \mathrm{Br}^- \rightleftharpoons \mathrm{AgBr} + \mathrm{Cl}^-$$

The bromide concentration required for this reaction can be calculated from the solubility products and the free chloride ion concentration:

$$[\mathrm{Br}^-] > \frac{K_{\mathrm{sp}}\,(\mathrm{AgBr})}{K_{\mathrm{sp}}\,(\mathrm{AgCl})} \cdot [\mathrm{Cl}^-] \gtrsim 10^{-3}\,[\mathrm{Cl}^-]$$

In contrast, the conversion of AgBr to AgCl can take place only if $[\mathrm{Cl}^-] \gtrsim 10^3\,[\mathrm{Br}^-]$. As the extent of conversion increases, the crystal lattice becomes more and more deformed and is ultimately disrupted with the formation of a new phase having a different morphology.

Converted halide emulsions offer particularly good developability because of their highly disordered crystal lattice. They have the disadvantage of pressure sensitivity, because the internal lattice imperfections are reinforced by deformation so that the latent image appears inside the grains rather than at the surface. Pressure points may show up, for example, as bright areas on a black-and-white paper.

Monodisperse Emulsions. The double-jet method allows controlled emulsion making. Emulsions with narrow grain-size distributions result in particular when precipitation takes place near the solubility minimum, i.e., at relatively low halide excesses. Nucleation occurs only within the first few seconds, and a certain number of stable nuclei are generated. Afterwards, all the crystals grow in a uniform way. Since the physical ripening step is omitted, the initial grain-size distribution remains virtually unchanged in the course of precipitation, so that "monodisperse" emulsions are obtained [14].

pAg-Controlled Double-Jet Method. In process-engineering terms, the making of a monodisperse emulsion requires holding the halide concentration constant at a very low level ($10^{-2} - 10^{-3}$ mol/L) over a long period in which balanced double jet addition of silver nitrate and halide solutions occurs. The only way to achieve this is with electronic metering devices using the halide concentration or the corresponding silver ion concentration $[\mathrm{Ag}^+]$ as control variable; this latter value is more easily measured as the potential difference U_{Ag} between a silver electrode and a reference electrode. The potential difference is given by the Nernst equation

$$U_{\mathrm{Ag}} = U_{\mathrm{Ag}^\circ} + \frac{RT}{F} \ln\,[\mathrm{Ag}^+]$$

where U_{Ag° is the standard potential of silver, R is the universal gas constant ($R = 8.31\ \mathrm{J\,K^{-1}\,mol^{-1}}$), T is the temperature in K, and F is the Faraday constant ($F = 9.65 \times 10^4$ C/mol).

The Ag/AgCl-electrode in 3 M KCl solution is used as reference electrode, relative to which $U_{Ag^o} = 589$ mV.

Hence $U_{Ag} = 589\,\text{mV} + 59(= 2.303 \cdot 298\,\text{K} \cdot 8.31\,\text{J K}^{-1}\text{mol}^{-1} \times 10^3/9.65 \times 10^4\,\text{C/mol})$ log $[Ag^+]$ mV at 298 K. As $-\log[Ag^+] = \text{pAg}$, $U_{Ag} = 589\,\text{mV} - 59 \cdot \text{pAg}$ at 298 K. The saturated calomel electrode which is also used has a 37 mV lower potential than the Ag/AgCl electrode at 298 K.

The pAg-controlled precipitation method makes it possible to obtain emulsion crystals not only of the desired uniform size but also of well-defined shape. As already noted, AgCl and AgBr both form cubic crystals, but AgBr crystallizes in a cubic lattice only when precipitated at a very slight bromide excess, that is, at pAg values < 7.5. If the bromide ion concentration during precipitation corresponds to a pAg > 8.5, the grains become octahedral. The reason for this behavior is the difference in the strength of bromide adsorption to the cubic (100) and the octahedral (111) faces. At pAg < 7.5, more bromide is adsorbed to the (100) than to the (111) faces, so that growth is inhibited at (100) faces relative to (111) faces; the octahedral faces thus grow faster and eventually disappear, and only the cubic faces figure as growth forms. In contrast, at pAg > 8.5, the (111) faces are more strongly inhibited by bromide ion, so that the cubic faces grow faster, leaving only the octahedral ones. In the intermediate range, the tetradecahedra bounded by the cubic and octahedral faces are stable crystalline forms [198]. All seven kinds of possible crystal forms of silver halides allowed by the symmetry of the cubic lattice have now been observed. They can be obtained by growth on cubic or octahedral crystals in the presence of certain organic compounds called growth modifiers [199].

Precipitation at low halide excesses, that is, near the solubility minimum, must be carried out so slowly that no new stable nuclei can readily form when the reactant solutions are added. From the economic standpoint, the shortest possible precipitation time is desirable. The duration of this step can be shortened if the inlet rates of the silver and halide solutions are increased either stepwise or continuously in the course of precipitation. The metering rate can be increased in proportion to the total area of the growing emulsion grains, but it cannot be raised indefinitely. Supersaturation and new nucleation will occur, at the latest, when the spacing between grains has become so great (because of the greater dilution) that added silver and halide cannot diffuse rapidly enough to the growth sites on the grain surfaces. As a countermeasure, silver halide solvents can be added to enhance the solubility of the silver halide, so that the diffusion path around the individual grains becomes longer and the formation of new nuclei is shifted toward higher dilutions. Examples of AgX solvents include:

(methionine)

(1,8-dihydroxy-3,6-dithiaoctane)

(1-ureido-3,6-dithiaoctane)

(imidazole)

The pAg-controlled process, the most modern used in emulsion making, offers high precision and even makes it possible to control within certain limits the number of stable nuclei formed in the nucleation phase (which is proportional to the reactant inlet rate and inversely proportional to the total solubility and the temperature). In this way, the precipitation time needed to attain a desired grain size can be calculated.

Core – Shell Emulsions. With pAg-controlled precipitation, grains of uniform size and shape can be obtained, and the internal structure of the crystals can be modified in a way that is largely uniform from grain to grain. This holds true especially for the halide composition, but also for photographically effective dopants of all kinds [200]. The simplest modification of the emulsion grain consists in a grain whose inner and outer zones differ in halide composition. The advantages of such a core – shell emulsion, with the core enriched in iodide and the shell depleted in iodide or free of that ion, were discussed in Section 2.3.4.3. The phase boundaries are especially important in this grain structure, since space-charge effects

at these boundaries are important in the formation of latent-image centers and can facilitate the separation of photoelectrons and positive holes. Emulsions have been developed that go beyond the simple core – shell principle, having multiple interfaces and multiple zones with different halide compositions and dopants. This approach makes it possible to vary the photographic behavior of emulsions widely and adapt them to other components of the photographic coatings. In addition to its effect on the sensitivity, gradation, and reprocity properties, the use of core – shell and multistructured emulsion grains also makes it possible to match the kinetics of development and coupling (e.g., of DIR couplers) to each other. This is a necessity with color films if high color brilliance is to be obtained through interimage effects, or extreme detail reproduction through edge effects.

Direct Positive Emulsions. The direct positive emulsions described in Sections 2.1.6 and 2.3.4 are a typical example of the pAg-controlled precipitation process with control of the grain structure. The incorporation of sensitivity specks in the grain interior is particularly successful when the crystals are regular in shape and homodisperse. Sensitivity centers need not always be present in the grain interior. An incorporated phase boundary such as AgCl – AgBr can have the same effect, that is, can topologically control the formation of latent-image centers [201], [202].

Redeposition of Lippmann Emulsions. In the older precipitation processes, there is always an overlap in time between nucleation, growth by direct deposition, and physical ripening. Ostwald ripening is suppressed with an approximately equimolar double-jet inlet of the reactants under pAg control, the silver halide grains grow to their final size solely by direct precipitation. In contrast, grain growth can also occur predominantly by Ostwald ripening if the silver halides are introduced not as salt solutions but as superfine so- called "Lippmann" or micrate emulsions with grain sizes smaller than 0.1 µm. If such an emulsion, which is relatively soluble, is blended with an emulsion having larger or more sparingly soluble grains, and if the mixing ratio, temperature, and complexing by the added silver halide solvents are selected appropriately, the micrate grains are dissolved and redeposited on the more sparingly soluble grains [203]. The pAg remains constant during deposition without any external control.

Tabular Grain Emulsions. Tabular emulsion grains, by virtue of their relatively large surface-to-volume ratio, are especially suitable for the adsorption of sensitizing dyes that impart the desired spectral sensitivity. In emulsion work, such tabular grains are characterized by the aspect ratio, the ratio of grain diameter to thickness, which can vary from grain to grain. The diameter is calculated by taking a circle having the same area as the projection of the crystal; the thickness is the distance between the two parallel (111) external faces [204]. Theoretically, it would be possible to attain an extremely high aspect ratio by making the tabular grains sufficiently thin. From the photographic standpoint, however, tabular grains are of interest only up to an aspect ratio of about 30 and with a thickness of about 0.1 µm. The reasons for this are: photoelectrons do not have an indefinitely long diffusion range; and large-area tabular grains become mechanically unstable, which leads to photographically problematic pressure phenomena such as fogged streaks where pressure has been applied. Even in the classical acid and neutral emulsions, the number of tabular crystals of various sizes is relatively high, and they normally occur along with other, irregular grain shapes. The newer tabular grain emulsions are distinguished from these by the fact that virtually all the grains are tabular. In order to produce such an emulsion, the maker must know the crystallographic structure of tabular grains. Despite their variety, nearly all observed crystal forms in commercial AgBr and AgBr – AgI emulsions can theoretically be attributed to just one type of possible structural defect in the AgBr lattice: stacking faults on (111) faces [205], [14].

The regular growth of a crystal of the rock salt type proceeds on (111) faces in such a way that the second and third lattice planes B and C are each displaced slightly from the first plane A, while the fourth lattice plane again lies exactly above the first (see Fig. 21).

A lattice plane of an octahedral face can "erroneously" fail to occupy its proper position, that of the third-from-last plane, taking up instead the position of the next-to-last. This can occur espe-

cially in the nucleation or initial growth phase. In other words, instead of the ABCABCABC arrangement, the lattice plane following B can grow in position A instead of position C. This "error" results in a stacking fault, with the consequence that the nucleus grows in a symmetrical manner, forming a mirror image relative to plane B. From its appearance, this crystal is called a twin. At the surface location indicated by arrow in Figure 21, where the twinning plane B intersects the surface, a trough forms.

Figure 21. Stacking faults on a (111) face

Figure 22. Simple octahedral twinning (schematic)
For explanation see text

Figure 22 A shows a crystal nucleus produced by twinning. The lower octahedron represents the regularly grown region; the upper one is the part grown after twinning. In reality, the upper portion is not an ideal octahedron but a region just a few lattice planes thick. The figure clearly shows, however, that troughs form at the surface locations pointed out by the arrows, where the twinning plane intersects the surface. There is a third trough behind the plane of the image (not visible). Further silver and halide ions can be easily deposited in these three troughs (Fig. 22 B); because this process is energetically favored. The trough faces therefore grow faster than the other faces, until finally the simple twin form (Fig. 22 C) is reached.

The situation is different if two stacking faults occur in quick succession on two parallel (111) faces. The resulting double twins have two troughs, which remain permanent features during the further deposition of silver and bromide ions and lead to strongly anisotropic lateral growth, that is, a tabular grain shape (Fig. 23).

Figure 23. Double twin (twin lamella)

The crystallographic precondition for the formation of tabular grains is accordingly the presence of two stacking faults on parallel (111) faces, that is, the occurrence of a twin lamella in the nucleation phase. Octahedral faces are produced at high pAg values (see page 34), while stacking faults occur chiefly at high inlet rates. If both conditions are established at the beginning of a precipitation, the grains produced will be almost exclusively tabular grains.

Figure 24. AgBrI crystals with epitaxially deposited AgCl

Epitaxy. The oriented growth of small quantities of a new silver halide phase on emulsion grains has long been employed to achieve photo-

graphically useful effects [206]. Such epitaxial growth can also be topologically controlled in several ways. Besides the crystallographic influences, the local halide composition of the host crystals can be decisive, and in addition "site directors," such as stabilizers and sensitizing dyes, can modify the epitaxial structures in a variety of ways [207]. Figure 24 shows, as an example, small AgCl cubes at the vertices of AgBr – AgI tabular grains. The cubes are produced by precipitation in the presence of a sensitizing dye. The formation of sensitivity specks and latent-image centers can be directed by those epitaxial overgrowths.

3.1.2. Removal of Soluble Salts

The soluble salts generated during precipitation, chiefly the excess halide, must be removed so that emulsions can be chemically ripened and after coating, crystallization of salts in the dried emulsion layers can be prevented.

Washing and Coagulation Processes. Formerly, the emulsion was solidified, cut into small pieces, and washed in running water down to a well-defined residual salt content. Currently, a coagulation process is generally used; this is more economic and also offers the photographically important advantage of concentrating the emulsion, since the coagulated precipitate can be dissolved in less water than was present in the initial volume.

For example, the gelatin can be precipitated with alcohol or high concentrations of inorganic salts, such as Na_2SO_4, $MgSO_4$, or $(NH_4)_2SO_4$. The amounts of salts required are smallest at pH values of 3 – 4. Low gelatin concentrations and high silver halide contents promote coagulation.

A more elegant method of coagulating the gelatin is to modify it chemically in such a way that it is only sparingly soluble in acids. This can be done by reacting the basic amino groups of the gelatin with acid chlorides, anhydrides, isocyanates, diketones, and similar reagents. The addition of 10 % of an acylated gelatin is enough to coagulate all the gelatin at pH 3. After the coagulated precipitate has been washed several times and decanted, the acylated gelatin is redissolved in water by raising the pH, and the original emulsion is reconstituted. The gelatin can also be coagulated at an acidic pH through the formation of coacervates with polymeric organic compounds that contain sulfo or carboxyl groups. The washed precipitate is then redispersed at $pH > 6$. Suitable polymers include polyesters of sulfosuccinic acid, poly(styrenepyridinesulfonic acid), or poly(vinylpyridinesulfonic acid); maleic acid – styrene copolymers; and copolymers of acrylic or methacrylic acid with their esters. In order that the coagulated precipitate can be uniformly washed, it must be in a solid but fine-grained form. The consistency of the precipitate can be controlled through the type of gelatin, the ratio of gelatin to silver halide, and the coagulation temperature. The degree of washing or the residual salt content of the precipitate can be determined by electric conductivity and pAg measurements. The pAg of each emulsion is adjusted to a specifically well-defined value with alkali halide after redispersion; it is crucial for the next operation, namely chemical sensitization.

Ultrafiltration. Ultrafiltration is a desalting method in which the gelatin need not be solidified or coagulated. It is a membrane process that can separate the alkali nitrate solution from the remaining emulsion in the liquid phase and is thus superior to the more complicated and hard-to-automate coagulation process from both engineering and economic standpoints. Ultrafiltration equipment with hollow-fiber modules has proven suitable for emulsion work. A hollow fiber module contains several hundred parallel capillary tubes made of polysulfone inside a cartridge. From a supply tank, which can also be supplied with fresh water, the emulsion is circulated through these hollow fibers. The salt solution permeates through the membranes and is withdrawn on the shell side of the cartridge. The separation limit of the membrane is around 30 – 50 kdaltons. The operation of ultrafiltration equipment is characterized by the pressure and the flow rates.

Figure 25 shows a flowsheet of an ultrafiltration unit employing the feed – bleed principle, in which two closed loops allow independent control of the flow velocity in the UF cartridge and in the feed vessel. Provision is also made for a reserve flow so as to permit cleaning. Of course, ultrafiltration can also be used for concentrating the emulsion. Low gelatin contents favor this

Figure 25. Ultrafiltration unit
a) Pump; b) Cartridge; c) Switch valve; d) Feed vessel; e) Salt solution

process. Ultrafiltration can also be carried out during precipitation or in between precipitation steps [208]. By concentrating the emulsion, this technique makes it possible to process relatively large quantities of silver halide per unit vessel volume.

3.1.3. Chemical Sensitization

The emulsion grains after precipitation and desalting are fairly insensitive. When they are exposed to light, latent-image centers are formed throughout the grain volume, preferentially at any lattice defects that are present. Early in the history of photographic emulsions, it was discovered that the sensitivity in the intrinsic absorption part of the spectrum can be enhanced by additional digestion of the washed emulsion at elevated temperature, especially if more gelatin is added.

Sulfur Sensitization. In 1925, S. E. Sheppard realized that the gain in sensitivity described above is due to labile sulfur compounds in the gelatin. After this discovery, it was found that thiosulfate, added in quantities of ca. 5 – 50 µmol per mole silver, is the compound that acts as sensitizer during chemical ripening or postdigestion. Initially thiosulfate is adsorbed to the surface of the silver halide as the complex $[Ag(S_2O_3)]^-$. The adsorbed complex then disproportionates to Ag_2S and sulfate. On exposure, latent-image centers consisting of a few silver atoms are formed preferentially at these Ag_2S sensitivity specks. Other sulfur compounds employed in digestion include thiourea, *N*-allylthiourea, and thiosemicarbazide. Sulfur sensitization depends on pAg, pH, and temperature. The usual operating ranges are as follows: pAg, ca. 7 – 9; pH, ca. 5 – 8; temperature, 45 – 65 °C. Digestion times are usually between 1 and 4 h. Much shorter ripening times of a few minutes in combination with higher temperatures of up to ca. 80 °C have also been cited in the literature.

Gold Sensitization. In 1936, R. Koslowsky achieved a markedly greater increase in sensitivity and a simultaneous improvement in latent-image stability by using gold(I) thiocyanate complexes in addition to sulfur sensitization. It is thought that a mixed gold – silver sulfide is produced in gold sensitization. This compound presumably lowers the number of silver atoms required for developability from about four to three or even two. The amount of gold needed is 2 – 20 µmol per mole silver. The combination of gold and sulfur sensitization with the stabilizer triazaindolizine, in particular, led to a marked improvement in emulsions.

The degree of chemical ripening is controlled by sampling the emulsion at intervals, submitting it in liquid state to sensitometric tests or coating it on a support, and performing photographic tests. Figure 26 illustrates the sensitometric changes occurring in digestion. The sensitivity increases, reaches a maximum, and may decrease again if digestion time continues. The gradation behaves in a similar way. The limiting factor is the photographically undesirable fog that occurs on prolonged digestion. The presence of fog suggests that larger silver aggregates, developable even without exposure, have been formed on some grains, Chemical ripening is stopped, e.g., by cooling or addition of a stabilizer when sensitivity is at a maximum and fog is still relatively slight.

Figure 26. Developed density D versus exposure ($H=I \cdot t$) after various digestion times
Inset: sensitivity and fog versus ripening time

Reduction Sensitization. The sensitivity of an emulsion can be greatly enhanced even without thiosulfate and gold. Digestion with suitable reducing agents, such as tin(II) compounds, ascorbic acid, hydrazine, or formamidinesulfinic acid has a sensitizing action. Reduction sensitization by *Wood's silver digestion method* is also very effective. In this process, apparently, the reducing capacity of certain reducing agents present in the gelatin is utilized at high pH and high silver ion concentration, i.e., a low pAg. Such reduction sensitizers as carbohydrates and aldehydes can be found in nearly all types of gelatin, so that reduction sensitization is thought to be involved to some degree in all forms of chemical sensitization. The sensitivity specks formed during reduction sensitization consist of silver. Photographically, the behavior of small and large reduction centers is totally different: small reduction centers act as hole traps, thereby diminishing recombination and not controlling the topography of the latent image. For this reason, such centers should preferably be incorporated in the interior of the emulsion grains. Larger reduction centers, in contrast, act as electron traps, similarly to the sensitivity specks formed in sulfur and gold sensitization. More intensive reduction sensitization in conjunction with gold sensitization, results in fog. Reduction centers can be produced with hydrogen too; which leads to an increase in sensitivity for some hours, especially in dry, degassed photographic films, and low-intensity reciprocity failure can be minimized.

Digestion in the Presence of Dyes. It used to be common practice not to add sensitizing dyes until just before emulsion coating. Currently, emulsions are often precipitated or at least chemically ripened in the presence of one or more dyes. In the first case the adsorbed dyes serve as growth modifiers, in the second they cover large areas of the grain surface during digestion and thus cause the sensitivity specks to be concentrated on the uncovered areas. Lowering the number of sensitivity centers should combat the "waste" of silver deposition and thus counteract any loss of sensitivity. The use of dyes as site directors for the topology of sensitivity specks, and subsequently that of latent-image centers, does not work with all the commonly employed sensitizing dyes.

3.1.4. Emulsion-Making Technology

In keeping with more complicated emulsion recipes, the standards of emulsion-making technology have become more stringent. Good emulsion quality and reproducibility are preconditions for meeting the high quality standards imposed on photographic products. Emulsion technology includes the following essential process steps:

1) Tempering

2) Metering
3) Stirring – mixing
4) Ultrafiltration (optional)

One source of difficulty is the necessity of working under muted red light or, once the sensitizing dyes have been added to the emulsion, in complete darkness. For this reason, manual operations are eliminated whenever possible, and emulsion plants make use of automation and process control systems where these are workable and economically acceptable. Process control computers handle the batching (weighing) of all ingredients, including water; temperature and flow-rate control; and monitoring of the desalting process.

3.1.4.1. Raw Materials

Even the lowest level of impurities in an emulsion can markedly impair the photographic result. Process equipment, peripheral equipment, and all raw materials used must therefore meet strict cleanliness and purity requirements.

Appropriate filtration units must deliver *air* free of both solid and gaseous contaminants, especially hydrogen sulfide. *Water* is usually treated on ion-exchange resins and must not contain any reducing agents. The specification for *silver nitrate* and *halides* is stringent, especially for heavy-metal impurities: the concentration of iron, copper, and lead must be < 1 ppm. The suitability of all feedstocks is ultimately judged through photographic testing.

Gelatin is still irreplaceable for emulsion making because of its unique combination of good physical and chemical properties, such as protective colloid action, halogen-accepting capacity, its ability to solidify below 30 °C, its hardenability, and swelling. Despite the animal origin and thus a varying composition of the raw materials, great improvements in the quality and re-producibility of photographic gelatin have been achieved. Inert bone gelatin, which offers the maximum freedom from photographically active constituents, predominates in emulsion making. Special modified grades of such gelatins are sometimes employed for particular applications (see page 38). In addition to gelatin, synthetic polymers are also used. Examples are cellulose derivatives, poly(arylic acid) derivatives, poly (vinyl alcohol), and polyvinylpyrrolidone. However, they are generally applied only as additives to improve the physical properties of the emulsion coatings; they are not so much employed in emulsion making.

3.1.4.2. Emulsion-Making Equipment

Photographic emulsions are usually prepared batchwise. The vessels range from hundreds to thousands of liters in capacity. To protect against corrosion, all vessels used for precipitation, coagulation, and chemical ripening, as well as all other equipment that comes in contact with the starting solutions or the emulsion, are made of stainless steel or, more recently, titanium. The corrosion resistance of austenitic stainless steel increases with increasing molybdenum content. Suitable materials of construction include those identified by the following Material Numbers: DIN 1.4439 (4 % Mo); DIN 1.4529 (6 % Mo); and DIN 3.7035 (Ti).

Normally, separate vessels are used for each process step (precipitation, coagulation, or ultrafiltration, and chemical ripening). The vessels have double walls and are equipped with electronic water-temperature controls as well as pAg and pH electrodes. The preferred bottom shape is conical so that even small starting volumes can be stirred without undue foaming. The silver nitrate and halide solutions can be fed via piping from several (at least two) feed tanks (also with temperature control) to the *precipitation vessel*. In the simplest arrangement, the reactants are delivered by gravity and fed through fixed or adjustable gate valves; for more exact control, metering pumps or flow-rate control systems (which may be pAg- controlled if appropriate) are employed. Because good mixing is very important – i.e., of the reactants with one another and with the gelatin solution, or with emulsion already present – a variety of methods are used to achieve adequate stirring and mixing. In addition to classical stirrers in the vessel there are techniques where the reactants are metered into a separate mixing chamber installed either in the tank itself or in an external pumped- circulation loop [209–213] (Fig. 27). The spontaneous ionic reaction then takes place in a well-defined space under relatively reproducible conditions, while the slower process of physical ripening takes place chiefly in the tank.

Figure 27. Precipitation system for photographic emulsions
a) Precipitation tank; b) Reactant feed tanks; c) Pump and mixing chamber; d) Metering controls; e) pAg electrode; f) pH electrode

The *coagulation tanks* also have high-performance stirrers so that the coagulated precipitates can be uniformly washed. Equipment in these tanks also includes pH, pAg, and electric conductivity measurement devices. After coagulation and washing water can be decanted or separated by filters, centrifuges, or hydrocyclones. Like all other water streams used for cleaning, it is intercepted and forwarded to silver recovery and clarification. For ultrafiltration, see Section 3.1.2.

Redispersion of the coagulated precipitates and chemical sensitiztion usually take place in a single operation. The *digestion tanks* feature precise temperature control; for controlled dissolution of the coagulated precipitates, they have pH control and, like the precipitation and coagulation tanks, are provided with pAg electrodes. They also permit the addition of sensitizing dyes. After chemical sensitization is complete, dyes, stabilizers, and preservatives are added to the emulsions. The emulsions are either filled in plastic bags and stored in cool rooms or rapidly solidified in cooling pans or on cooled belt conveyors then held in sealed metal or plastic tanks located in cool rooms (between 2 and 5 °C). Under these conditions, emulsions can be held for several months.

Continuous Emulsion Making. Continuous operation, at least in the *precipitation step*, is useful in view of the desired uniformity and exact reproducibility of photographic emulsions. In the simplest case, the reactants ($AgNO_3$, halide, and gelatin solutions) are continuously metered into a mixing vessel, while the same amount of emulsion is discharged from the vessel, for example by way of an overflow, so that the volume remains constant. In this continuous mixed-suspension, mixed-product-removal (CMSMPR) process a steady state is reached after a certain transient time period; the grain-size distribution and grain shape of the emulsion then remain constant [196].

In other continuous precipitation processes, the precipitation tank is replaced by a tubular reactor, which has at least one but usually several mixing chambers in a cascade arrangement;

Figure 28. Grain size plots and electron micrographs of three emulsions

a wide variety of mixing chambers have been described. The precipitation reaction itself takes place in the reactor, while ripening occurs in pipes, which may be provided with static mixers. The length of piping corresponds to the needed ripening time [6].

Continuous processes have been described not only for precipitation and ripening but also for *coagulation* and *washing* as well as chemical sensitization. Continuous salt removal by ultrafiltration is particularly easy to manage.

The continuous processes offer some advantages over the batch processes: better reproducibility, higher production rates, capability of automation, quicker detection of malfunctions, and as a result lower emulsion losses. They have, however, the disadvantage of inflexibility. Different types of emulsions demand substantial equipment modifications; for example, the number of mixing chambers and the length of the ripening pipe runs. With regard to freedom of formulation, batch emulsion making is superior to the continuous processes. Another problem lies in the thorough cleaning required for emulsion-making equipment; a tubular reactor with its large wall area is inferior to a tank in this respect.

3.1.4.3. Test and Measurement Methods for Photographic Emulsions

In addition to the many photographic tests, which also include simulated long-term storage under extreme conditions, a number of nonphotographic measurement techniques are also used [214]. The most important characteristic of an emulsion is the *grain-size distribution*. Initially grain-size analysis was carried out by means of electron micrographs, but this method was relatively difficult. Today this analysis can be done easily and quickly by an *electrochemical technique* developed specially for silver halide emulsions [215], [216]. A highly diluted emulsion is used, the grains of which are allowed to settle onto a substrate, the preparation is placed in an electrolyte, and a platinum tip acting as

negatively charged electrode is guided over it. When the tip makes contact with a grain, the latter undergoes complete spontaneous reduction. The electric flux is a direct measure of the grain volume.

Figure 28 shows three emulsions with very different grain-size distribution, illustrating the capability of the electrochemical technique as a complement to electron microscopy.

In addition to the grain size and shape, the *halide distribution in the grains* is photographically relevant. It can be measured in integral form by X-ray diffraction techniques. Crystallographic phases differing in halide composition are often reflected in separate peaks. The resolution needed for this purpose can be improved substantially by using synchrotron orbital radiation (SOR) instead of X-rays for structural analysis [217]. Synchrotron radiation is emitted by electrons orbiting in an accelerator; it features high intensity and collimation. These two measurement methods are compared in Figure 29. While the principal peak (97 mol % AgBr, 3 mol % AgI) is measured by both techniques, only the SOR measurement reveals the existence of a second mixed phase (84 mol % AgBr, 16 mol % AgI).

Figure 29. The (200) reflection of AgBrI microcrystals X-ray=Guinier measurement with Cu $K_{\alpha 1}$ radiation. SOR=synchrotron measurement with $\lambda = 0.1274$ nm [218] recalculated to Cu $K_{\alpha 1}$

In principle, the halide distribution in single emulsion grains could be determined as well; for example, by electron-beam microanalysis. In this technique, a grain or a thin-section specimen of a grain is scanned with an electron beam, and the concentration of halides is determined from the intensity of the corresponding X-rays emitted. Portions of the grain near the surface can also be investigated by SIMS and ESCA. Single-grain analyses are relevant only for homodisperse emulsions, because the results cannot be representative in other cases.

Measurements that can provide information on the formation of the latent image are of special interest. Important quantities are the concentrations and lifetimes of photoelectrons, positive holes, and interstitial silver ions. Microwave photoconductivity, dielectric loss, and the Dember effect are suitable analytical techniques. The measurement of luminescence, which can identify the energy level of lattice defects and recombination centers, give additional information. The technique is also suitable for the study of spectral sensitization and stabilization. Radicals of sensitizing dyes generated by exposure and dopants, often present at levels of a few atoms per microcrystal, can be detected by ESR spectroscopy [214].

3.2. Emulsion Supports

The substrates under emulsion layers must meet high standards, especially with respect to their physical properties. These include high transparency, high rupture and tearing strength, freedom from curl (wet and dry), stiffness, high modulus of elasticity, antistatic qualities (to guard against electrical discharges), good dimensional stability, and low coefficient of friction.

The constituents of the support must not affect the photographic properties of the various materials in the emulsion layer or the sensitometry of the photographic film. In addition the gelatin-based emulsion layer must also adhere well to the support during every stage of use and processing.

These diverse requirements are met through the proper selection and fabrication of the film base and the use of special, nonphotosensitive auxiliary layers on it.

The only bases now commonly used are *papers* [with baryta (barium sulfate) or polyethylene coating] and *plastic films* (cellulose triacetate or polyester). *Glass plates*, despite their undisputed advantages (dimensional stability,

freedom from curl), have lost much of their former importance because of their undeniable disadvantages (fragility, weight, space required). They are still used to a limited extent in some special fields. Emulsion- coated textiles find limited application as decorative materials (e.g., coated linen).

Films, chiefly polyester, opacified with white pigment such as TiO_2 are now coming into use for display materials (dimensionally stable substitute for paper).

3.2.1. Films

3.2.1.1. Properties of Film Materials

Cellulose Nitrate. When Kodak introduced cellulose nitrate as an emulsion support at the end of the 19th century, the basis was laid for the widespread use of photography today; ie., a light, flexible recording medium was used instead of the clumsy glass plates used up to that time. Motion-picture photography, above all, is possible only with flexible film as emulsion support (motion-picture and narrow-gauge films). Later, however, the high flammability of cellulose nitrate led to a number of catastrophic fires, which ultimately led to the development of less flammable films with no tendency to ignite spontaneously. Today, as far as is known, cellulose nitrate film base is no longer manufactured. For reasons of safety, most archival films, especially motion pictures, have been transferred from this medium to cellulose triacetate-based films.

Cellulose Acetate. The first "safety films," made from acetone-soluble cellulose acetate with 54 – 56 % combined acetic acid content (2^{12} acetate), were not competitive with cellulose nitrate, being inferior to it in mechanical properties and dimensional stability. These qualities were later improved by increasing the degree of acetylation. Today, virtually all miniature, roll, motion-picture, and narrow-gauge films use a triacetate base with ca. 61 % bonded acetic acid, which is soluble in a 9 : 1 solution of dichloromethane and methanol.

Cellulose is acetylated with acetic anhydride, either in a solvent that dissolves the product cellulose acetate or in a medium such as xylene, which acts as a nonsolvent, leaving the fibrous structure of the feed cellulose (e.g., cotton linters) unchanged. The two types of cellulose acetate are equally suitable for use as emulsion supports.

Cellulose Mixed Esters. Mixed esters of cellulose with acetic and homologous carboxylic acids are less water-sensitive than pure cellulose acetate. Cellulose acetates butyrates, in particular, found practical use. Today they are employed only for special-purpose films (e.g., duplicating sheet film, where the acetone solubility of the support allows special techniques such as butt splicing).

Polystyrene. Films made of polystyrene have very low water uptake, but increased temperature sensitivity limits their dimensional stability (theoretically better than cellulose triacetate). These films have a great sensitivity to kinking; irreversible clouding results from even slight kinking. Even though this support has now been improved, it is of little practical importance.

Polycarbonate. Because of their low water sensitivity, polycarbonate supports made from bisphenol A [2,2-bis-(4-hydroxyphenyl)propane] and phosgene appeared highly suitable for reprographic films when they first became available. But the relatively low modulus of elasticity meant that these bases had inadequate resistance to the tensile forces of emulsion layers, and hence poor dimensional stability. Only small amounts of polycarbonate films are now manufactured for use in photographic materials. Polycarbonate pigmented with TiO_2 has now been largely supplanted by similarly pigmented polyester.

Polyester. In this context, "polyester" always denotes poly(ethylene terephthalate) (PETP). Decades of effort aimed at improving dimensional stability have resulted in the worldwide use of this support, which combines all the desired features: high modulus of elasticity, low water absorption, and good performance at high temperatures. Special PETP supports for photographic materials are manufactured, e.g., by Du Pont (Cronar), ICI (Melinex), Kodak (Estar), Agfa-Gevaert (Gevar), 3 M, Fuji, Toray, and Teijin. These bases are absolutely insoluble

in common solvents. Polyester supports are employed for graphic-arts films and reprographic materials because of their optimal dimensional stability; they are used for X-ray films because they are stiffer than cellulose acetate. Finally, the high mechanical strength of PETP makes it possible to produce thinner supports for narrow-gauge films (Fuji). Their acetaldehyde content (resulting from thermal conversion of ethylene glycol during synthesis) can be detrimental to the potential use of PETP in color negative films; acetaldehyde can modify the color balance if it reacts with dye couplers, especially the magenta coupler. In order to minimize the acetaldehyde content of the substrate, the manufacturing conditions must be closely controlled.

3.2.1.2. Manufacture of Photographic Film Bases

Modern emulsion supports are produced by a wide variety of methods. *Cellulose triacetate* is fabricated by solution casting (→ Films, Chap. 2.1.). The operation is performed in drum or belt casting machines, the latter usually having belts made of highly polished stainless steel. The solvent is a mixture of dichloromethane and lower aliphatic alcohols such as methanol, 2-propanol, and butanol. Solvent recovery takes place in brine chillers or on activated carbon. Plasticizers (usually phosphates such as triphenyl phosphate) are added not to improve the mechanical properties but to reduce the flammability and water absorption (so as to minimize longitudinal expansion when the humidity is high). Dyes are added to prevent halation (see Section 3.2.1.6) and to combat *light piping*. (Light piping means that light may penetrate into the film inside its cartridge, passing through the edges of the leader, which protrudes from the cartridge, and into the transparent support. It experiences total reflection at the boundaries of the base, thus propagating further into the film and causing pre-exposure.) If a blue or, better, a black absorbing dye is incorporated into the support, the light is absorbed and light piping is suppressed.

Common film thicknesses are ca. 0.09 mm for roll films, 0.13 mm for miniature and narrow-gauge films, 0.14 mm for motion-picture films, and 0.19 mm for studio and sheet films.

In contrast, *polyester film base* is extruded from the melt at around 300 °C and biaxially stretched sequentially (→ Films, Chap. 2.3.2.), usually first in the longitudinal and then in the transverse direction. The film is then tempered at about 200 °C (thermofixation). Polyester film-base thicknesses are ca. 0.10 mm for graphic-arts and reprographic films and ca 0.18 for X-ray films. The methods used to produce polyester granules and films have continuously been improved in recent years. The price for PETP supports is now only about half that of equally thick cellulose triacetate supports. As a result, the question whether to use PETP bases for miniature, roll, and motion-picture films is being reexamined, even though some important technical problems remain to be solved. Examples are: precurvature, developing better cutting and perforating dies for this very tough base, devising antistatic coatings with adequate conductivity and mechanical strength. One problem not yet dealt with is how to control the cold creep of PETP film ("core setting" effect); i.e., the property of the film base to take on an irreversible curvature when rolled up. Poly(ethylene terephthalate) does not lose this curvature in wet development whereas cellulose triacetate does. Recently, however, PETP films have been subjected to tempering in the rolled-up stage in order to impart a negative precurvature; thus, the aforementioned difficulty has been avoided, at least over a long span of time; however, the remaining core setting is too strong, thus it is not appropriate to use PETP as a support for miniature films. PETP bases are already in use for some motion-picture films (because they have a larger winding diameter), for some roll films (e.g., ORWO negative films), and some sheet films.

Because photographic emulsions are sensitive to a great variety of contaminants, the machinery and fabrication rooms involved in the manufacture of film bases (including subbings and backings) have to meet extraordinarily stringent requirements on cleanliness. Special or even extreme purification and filtration of air used in the machines and present in the rooms – particularly the air used for drying the film and coatings – is an obvious measure, as are special lint-free clothing, clean rooms, and air-looks.

3.2.1.3. Subbings

The hydrophilic binders (nearly always gelatin) used with light-sensitive silver salts cannot adhere to hydrophobic emulsion supports. Good adhesion of the wet or dry emulsion is, however, an indispensable condition for the use and processing of photographic materials, especially the graphic-arts types. The needed adhesion is ensured by "subbing", in which the film surface is rendered hydrophilic by chemical or physical means, through the incorporation of hydrophilic colloids, or by multilayer systems in which the hydrophilicity increases from layer to layer. In difficult cases, especially with PETP, several approaches are combined. Achieving optimal adhesion during every stage of use and processing is one of the most serious problems in the manufacture of emulsion supports, and accordingly the patent literature in this area is quite extensive [219].

Cellulose Acetate Film Bases. All cellulose acetate bases now in use have hydrophilic colloids, usually gelatin, incorporated into the surface. These layers are applied as gelatin solutions that contain organic solvents as swelling agents for cellulose triacetate.

To facilitate drying, the swelling agents used have the lowest possible boiling points. Acetone is most common; sometimes it is mixed with dichloromethane. The solutions also contain a gelatin solvent, usually water (ca. 3 – 20 %), along with lower aliphatic alcohols such as methanol or ethanol. The crucial factor for surface swelling is the acetone – alcohol – water ratio. It varies usually between 60 – 70 : 10 – 20 : 2 – 3 vol %, depending on gelatin content which is in the range of 7 – 14 wt %.

To be stable at all in such predominantly organic solvent systems, the gelatin must be largely salt-free. Salt-free gelatin is produced by complete deionization, for example on ion-exchange resins. Acidic or alkaline stabilizing agents are also needed; examples are acetic, phthalic, salicylic, or maleic acids. Subbing solutions often contain hydrophobic polymers, such as cellulose nitrate or cellulose acetate, which improve the attachment of the subbing to the surface of the film base. Finally, gelatin hardeners are added.

If applied in quantities above a certain threshold level, cellulose nitrate catalyzes the hydrolytic decomposition of the triacetate substrate with the liberation of acetic acid ("vinegar syndrome" [220], [221]). This effect must be taken into account in the archiving of (motion-picture) films on a triacetate base.

The surface of cellulose acetate films can also be rendered hydrophilic by corona discharge or saponification [222], but these methods are no longer used.

Polyester Films. Because PETP films do not swell properly in the common organic solvents, the development of subbings for this material has been far more difficult. In practice, quite a variety of approaches are employed. Most frequently double-layer systems with increasing hydrophilicity are used, in which the first layer contains synthetic polymers and the second is essentially gelatin. As a first layer, for example, vinylidene chloride – methyl acrylate – itaconic acid copolymers (91 : 10 : 2) combined with poly(ethyl acrylate) in aqueous dispersion are applied before stretching [223]. The layer is then anchored to the film surface and incorporated into it during stretching. An adequate second layer is a 2 % gelatin solution applied after stretching. Other methods of subbing use soluble polyesters, such as poly(ethylene isophthalate) [224], applied from chlorohydrocarbon solutions after stretching, as the first coating. Such layers attach to PETP by adhesion. The second layers contain cellulose nitrate and gelatin.

The adhesion of the relative hydrophobic first coatings can be further improved by various pretreatments. Examples include oxidizing processes (e.g., with chromosulfuric acid, permanganate, peroxides, or a flame treatment of the film surface with an oxygen excess), corona discharges, UV and high-frequency irradiation, and swelling with special agents (e.g., phenol, resorcinol, chlorophenols [225], chloral hydrate, and chloroacetic acid). Swelling agents are sometimes added directly to the first subbing layer [226]. Most of the swelling agents suited to PETP are, however, not physiologically innocuous – in particular polyphenols and halogenated polyphenols so that special practices are necessary in manufacturing.

Efforts are being made to achieve good subbing with a single-layer system. In addition to

gelatin and a special polymer, such formulations contain one of the swelling agents listed above if the coating is to be applied after drawing [227]. If the subbing is applied before stretching or between the longitudinal and transverse stretching steps, no swelling agent is required [228].

3.2.1.4. Curl

After coating with a photographic emulsion, an initially flat film base will tend to curl toward the emulsion side. The amount of curl depends on the thickness and stiffness of the support as well as the thickness, composition, and drying of the emulsion. In practice, the tensile forces produced are exactly offset if the back of the support has a similar coating. In the simplest instance, such as X-ray films, the film is coated with *emulsion* on both sides. An "empty" gelatin layer (i.e., a plain gelatin layer without photographically sensitive components) on the back of the support is called a *noncurl (NC) coating*. Noncurl coatings are used on roll, studio, and reprographic films.

Because the gelatin NC coating is easily damaged, this system initially could not be employed on films processed in continuous-transport machines. Originally only motion-picture films were processed in these machines, but nowadays this also holds true for narrow-gauge and miniature films (i.e., 8- and 35-mm films). If the emulsion exerts too great a tensile force on these films, which causes a strong curvature of the film base to the emulsion side, the film base is precurved in the opposite direction by treating it on the back with swelling solvents such as acetone. The precurvature can be decreased and controlled through mixing with nonswelling solvents or through the use of high temperatures for post drying.

3.2.1.5. Antistatic Coatings

Film bases are extremely hydrophobic and tend to collect electrostatic charge. Charges are generated by friction, but especially when two surfaces separate after being in close contact; for example, when the emulsion and back sides separate during rewinding or unwinding. The discharges that follow lead to undesired and harmful fog, which takes the form of dots in the case of positive charging and branching lines in the case of negative charging [229]. There is a danger of creating such marks whenever the material is light-sensitive: during coating, cutting, packaging, use, and processing. It increases with increasing photographic sensitivity of the emulsion, increasing fabrication rate, and decreasing atmospheric humidity. The danger is especially great for single- coated films and for polyethylene- coated (resin- coated) photographic papers. Because gelatin is more hydrophilic, materials coated on both sides have much less tendency to static discharges.

Miniature, motion-picture, and narrow-gauge films are generally provided with antistatic backings for this reason. Charging can be prevented or minimized as follows:

1) Reduce the contact between the emulsion and backing through the incorporation of discrete particles ("spacers") into the emulsion; of i.e., photographically inactive inorganic pigments or small plastic spheres (usually methyl methacrylate), which protrude partway out of the uppermost layer.
2) Equalize the contact potentials of all possible contact partners.
3) Dissipate the electrical charges by lowering the surface resistance.

The most effective, and most widely used, approach is to lower the surface resistance [230] by application of conductive backings. Surface resistance values of $10^8 - 10^9\ \Omega$ per square at 50 % R.H. are generally sufficient. Most conductive backings contain polymeric film-forming electrolytes, usually alkali salts of polymeric carboxylic or sulfonic acids; examples are copolymers of acrylic or maleic acid [231], polystyrenesulfonic acid [232], or polymers with a quaternary nitrogen such as poly-2-*N*-methylpyridinium sulfate [233]. These antistatic coatings can be anchored to the back of the film base if appropriate swelling agents or swelling solvents are included in them. In the best case, a single solution can serve as antistatic and noncurl coating. Coatings with conductive carbon-black offer particularly good antistatic properties. They also have the advantages that their surface resistance is independent of the ambient humidity, and that they protect against halation (see Section 3.2.1.6).

But removal of such coatings requires an alkaline pretreatment in processing. Alkali-soluble high-molecular-mass compounds such as cellulose acetate hexahydrophthalate are used as binders [234].

Organic semiconductors, such as polyanilinium salts [235], vanadium pentoxide [236] and doped metal oxides, such as SnO_2 doped with antimony [237], have found use in humidity-independent permanent antistatic coatings on various microfilms. Important features of these materials include conductivity of the backing even after processing, which helps to prevent dirt adhering to the base.

3.2.1.6. Antihalation Coatings

Halation results from both reflection and diffusion (for diffusion halation). *Reflection halation* produces a halo effect in the developed film; it results from light rays reflected at the interface between media that differ in refractive index, mainly at the back of the film base. Suitable dyes, located in various layers of the overall system, can absorb this light. Characteristic of halation dyes are their content of acid groups in the molecule. By virtue of this they can be dissolved and eliminated from the layer during development.

Black layers of colloidal silver are often placed between the emulsion and the support to absorb reflected light. This approach, however, can be used only if the processing includes a bleaching bath in which this silver dissolves (black-and-white reversal films, color materials). Many black-and-white negative films have *antihalation undercoats* (AHU coatings), which contain dyes that are dissolved and bleached in the developer; hence, no bleaching bath is required.

The film base is dyed gray (*gray base*) when a neutral density of about 0.2 in the developed film will not pose a problem (miniature black-and-white negative films). The dyes used for this purpose have the most uniform absorption possible over the entire spectrum. Nearly all other miniature films, as well as roll and narrow-gauge films, have a lower gray-base density of ca. 0.04 in order to improve light-tightness in cartridges or cassettes (to prevent light piping; see above). Roll and sheet films with gelatin-based NC coatings (see Section 3.2.1.4) can have water-soluble dyes, such as acid green, pan yellow, or acid fuchsin, added to them in order to provide additional antihalation protection. When NC coatings or dyed undercoats cannot be employed, alkali-soluble backings containing carbon-black or appropriate dyes can be used as an alternative to black layers (e.g., in motion-picture films). Binders for these coatings are polymers with free carboxyl groups, which are again dissolved and removed during processing in alkaline baths.

3.2.1.7. Friction-Control and Protective Coatings

In order to avoid malfunctions in film transport in the camera, certain types of films, such as miniature and narrow-gauge films, must have a low coefficient of friction. Lubricants are coated on both the emulsion side and the back. Friction-control coatings on the back usually contain waxes (carnauba wax, montan waxes) and simultaneously improve the abrasion resistance of antistatic coatings and alkali-soluble antihalation coatings. Because the solvents involved (carbon tetrachloride, trichloroethylene) are toxic, attempts have been made to incorporate disperse lubricants directly into the antistatic or antihalation coatings.

3.2.2. Papers

Photographic paper bases can be classified as follows:

1) Resin-coated (polyethylene-coated) papers
2) Barium sulfate (baryta) coated papers
3) Lacquered papers
4) Uncoated papers for direct emulsion coating

Combinations of these treatments are also possible; for example, paper resin-coated on both sides can be given an additional baryta coating. The only treatments of importance are resin and baryta coating. The types of photographic paper bases common in the industry are as follows (basis weight of uncoated paper is given in grams per square meter).

Document paper, baryta- coated	50 – 110
Semi-weight paperboard, baryta- coated	120 – 159
Paperboard, baryta- coated	160 – 250
Papers for phototypesetting, resin- coated	65 – 90
Papers for diffusion transfer process, resin- coated	90 – 125
Semi-weight paperboard, resin- coated	120 – 159
Paperboard, resin- coated	160 – 200

3.2.2.1. Properties

Physical Properties. The most important physical properties are surface finish and formation, tint and opacity, stiffness and structural strength, thickness, curl, and freedom from physical contaminants.

The *surface finish*, which is produced by one of the treatments listed, is crucial for obtaining the desired surface quality in the final image (high-gloss, matt, lustre, etc.). The *formation* (as a property of the paper base) is among the factors controlling the uniformity of the final image.

The *tint* of the support must be precisely matched to the emulsion that will be applied, so that undesired color deviations can be avoided. High *opacity* in the support prevents the perceived color from changing when the photo is viewed on a dark background.

The *stiffness* of the paper is important chiefly to the consumer, especially in the case of large formats. The *structural strength* must be high when the material is to be processed in a modern developing machine.

Rigorous standards apply to *uniformity of thickness*, to guarantee the quality of emulsion coating and the trouble-free processing of roll and sheet papers.

Since the emulsion is coated on one side only, the gelatin usually exerts strong tensile forces. These must not produce curl in the print. Curl is opposed by the *stiffness of the support*, the *negative curl* in resin- coated papers (controlled by the density of the polyethylene resin), and gelatin- containing *noncurl coatings* on the back of the paper.

Physical contaminants can be directly visible in the finished print or may impair the surface of the paper in such a way that local disturbances of the emulsion that can be seen in the print. The same applies to defects such as impressions and other unevennesses on the paper surface.

Chemical Properties. The most important chemical properties are photochemical inertness, ability to adhere to the photographic emulsion, and stability with respect to developer solutions (hydrophobility).

All components of the support must meet strict requirements with regard to *photochemical inertness*. Constituents that initiate redox reactions in the emulsion ("chemical fog") or can influence other reactions must be excluded. Defects include not only local impurities containing metals or sulfur, but also volatile constituents or those able to migrate, which can lead to fog when photosensitive papers are stored for long periods (as they usually are). Ordinary methods of chemical analysis are hardly suitable for detecting such impurities, because photographic emulsions are far more sensitive to them than are the analytical methods [238]. Sensitometric tests with special test emulsions and suitable processing baths are carried out for a variety of impurities.

The *adhesion* of the photographic emulsion is improved by agents in the baryta coating or by treatment of the resin coating ("corona discharging" or subbing).

Stability to developing and fixing baths is achieved by rendering the paper base hydrophobic with resin-based or fatty substances; thus shortening the time required for processing baryta- coated paper. In resin- coated supports, the penetration of developer solution is prevented at the cut edge, where the paper base is exposed; otherwise, an unattractive brown streak would occur at the edge of the print.

3.2.2.2. Manufacture and Coating

All photographic paper bases, regardless of the treatment carried out before sensitization, begin as fiber-base paper made on endless-wire (foundinier) machines (→ Paper and Pulp, Chap. 7.2.3.).

They are made from highly bleached wood pulp (sulfite or kraft process, softwood or hardwood). Refining is optimized with regard to surface finish and mechanical strength; the freeness can be characterized as cut/short-fibered, between 30 and 45° SR (→ Paper and Pulp, Chap. 6.1.4.). The degree of internal sizing is

far greater than in other fine papers (writing and printing papers), so that the paper will be sufficiently hydrophobic for the subsequent processing operations.

Surface sizing is performed such as to match the subsequent operation (baryta or resin coating) and combines functions such as hardening, adhesion, and conductivity. The paper is compacted (calendered) in order to produce the required surface properties.

Important properties of the paper base include

1) Thickness and basis weight
2) Uniformity of thickness and basis weight profiles
3) Moisture content and uniformity of moisture content profile
4) Finish and smoothness (also after coating)
5) Stiffness and structural strength
6) Hydrophobicity
7) Tint
8) Adhesion of subsequent coating
9) Freedom from photochemical and mechanical contaminants and defects

The paper-base formulation is always matched to the special requirements of the end product, i.e., the photographic paper. The paper support is thus regarded as only one portion of a whole system and cannot be arbitrarily replaced [239].

Some typical paper-base formulations are illustrated in what follows.

Paperboard for baryta coating (240 g/m^2)

Pulp:
70 % softwood sulfite pulp
30 % hardwood kraft pulp

Internal sizing (relative to pulp):
1.5 % resin size
0.8 % sodium stearate
1.0 % gelatin
0.5 % melamine – formaldehyde resin
1.5 % aluminum sulfate
0.2 % optical brightener

Surface sizing:
4 % aqueous gelatin solution

Paperboard for resin coating (175 g/m^2)

Pulp:
30 % hardwood sulfite pulp
50 % hardwood kraft pulp
20 % softwood sulfite pulp

Acidic internal sizing (relative to pulp):
1.3 % sodium stearate
1.0 % polyacrylamide
1.0 % aluminum sulfate
3.0 % titanium dioxide
0.1 % optical brightener
0.4 % polyamineamide – epichlorohydrin resin

Alternatively :

Neutral sizing (relative to pulp):
1.5 % starch
0.5 % alkylketene dimer
1.0 % polyamineamide – epichlorohydrin resin
0.1 % optical brightener

Surface sizing:
Starch solution or poly(vinyl alcohol) solution, optical brightener, salt

Baryta Coating [240]. The baryta coating consists of barium sulfate, as pigment, and a binding agent, chiefly gelatin. Dyes and optical brighteners are added to produce the desired color location. Special agents ensure the adhesion of the subsequent emulsion coating.

The baryta coating is applied in one or two layers. These are leveled with brushes, air knives, or bars and dried in a festoon or channel dryer (→ Paper and Pulp, **A 18**, and Fig. 30). The baryta-coated paper is calendered or embossed, depending on the finish desired in the photographic paper.

Figure 30. Schematic diagram of a brush-type coating machine with festoon dryer for the application of baryta coating to photographic paper base
a) Unwinding; b) Coating station; c) Tension rolls; d) Ascending pin conveyor; e) Festoon dryer; f) Descending pin conveyor; g) Windup

A typical baryta coating (50 % solids content) has the following composition:

45 kg barium sulfate
15 kg gelatin
0.04 kg citric acid for pH adjustment
0.2 kg chrome alum (hardener)
0.01 kg optical brightener
toning dyes

Figure 31 shows the structure of the product.

Figure 31. Schematic cross section of a baryta-coated paperboard base
a) Paper base; b) Top sizing; c) First baryta coating; d) Second baryta coating

Resin Coating. Fiber-base paper is laminated on both sides with polyethylene in an extrusion machine with a wide-slot die (Fig. 32) [241–244]. If necessary, the back side can be printed before coating (b). The front and back resin coatings are applied in separate laminators (d, e). The surface of the paper is treated with corona discharges (c) just before coating in order to improve the adhesion of the resin.

Figure 32. Schematic diagram of a tandem extrusion coating machine with post aqueous coating facilities for two-sided resin coating of photographic paper base
a) Unwinding; b) Back-side printing press; c) Corona treatment for improved adhesion; d) Back-side laminator with chill roll; e) Front-side laminator with chill roll; f) Postfinishing, i.e., application of functional coating; g) Dryer; h) Windup

Immediately after the polyethylene melt is applied, the film is rapidly solidified on a chill roll. The resin coat is imprinted with the surface of the chill roll; accordingly, this step determines the finish characteristics of the final print (glossy, matt, lustre) as well as the finish and smoothness of the back.

Low-density and high-density polyethylenes (LDPE and HDPE) of high purity or mixtures of these are used. The back of the support is generally coated with transparent polyethylene. The resin for the front coating usually contains titanium dioxide, which enhances the line sharpness of the final print. Toning pigments and optical brighteners are added to adjust the tint. Special grades (diffusion papers) have carbon-black pigment added to the resin for the front coating.

The curl of the finished photographic paper base is controlled by adjusting the density of the polyethylene resins used for the front and back coatings. If the support is to be coated with emulsions that generate particularly strong tensile forces but must nontheless remain flat over a wide range of relative humidity, noncurl coatings are commonly applied. They are applied especially to papers with raw basis weights between 60 and 100 g/m^2 and top of the back resin coating.

If necessary, other functional layers can be applied on the resin, for example subbings, writability aids, and antistatic coatings. Figure 33 shows the structure of the product.

A typical composition of the polyethylene coating of a paperboard is as follows:

Front , 32 g/m^2 :
80 % LDPE
10 % HDPE
10 % titanium dioxide and pigments

Back , 30 g/m^2 :
65 % LDPE
35 % HDPE

Subbing :
2 % aqueous gelatin solution

3.2.2.3. Packaging, Storage, Transportation, Manufacturers

Photographic paper bases are packaged as machine-width rolls in polyethylene shrink-wrap; they are usually stored on end in climate-controlled rooms. The rolls are generally transported, on end, on special pallets in sealed containers, rail cars, and trucks. Packaging, storage, and transportation conditions must be such as to prevent variations in moisture, mechanical damage, and contamination [245], [246].

Suppliers. Major suppliers of photographic paper bases (without emulsion) include the following:

Fuji Photo Film Co., Tokyo, Japan (resin-coated bases)
James River Corp., High Wycombe, Bucks, United Kingdom (baryta- and resin- coated bases)
Mitsubishi Paper Mills, Tokyo, Japan (baryta- and resin- coated bases)
OJI Paper, Tokyo, Japan (resin- coated bases)
Felix Schoeller jr., Osnabrück, Germany (fiber-base, baryta- coated, and resin- coated bases)
Schoeller Technical Papers, Pulaski, N.Y., United States (fiber-base, baryta- coated, and resin- coated bases)
Freiberger Zellstoff- und Papierfabrik, Weissenborn, Germany (fiber-base and baryta-coated bases)
Serpukhov, former Soviet Union (fiber-base, baryta- coated, and resin- coated bases)

3.3. Coating

Exact Coating Thickness. Extremely small thicknesses, down to 10^{-4} mm (dry thickness), must be precisely reproduced. Unevenness in the thickness of a single layer can lead to variations in the density, that is, spots. In a color film, an error of a few percent in coating thickness can cause a color imbalance.

Freedom from Coating Defects. Even small flaws, such as bubbles, streaks, gaps, dust particles, agglomerations of coating material etc., can render a photographic material unserviceable, because enlargement (by a factor of 200 in the case of a motion-picture film) will make them distinctly visible. A high degree of cleanliness, especially the elimination of dust, is thus a vital requirement. In addition to finished product quality control, a number of flaw-detecting instruments are built into the coating machine in order to ensure defect-free operation.

Multiple Coatings and High Speeds. Nowadays color films, for example, can consist of as many as 15 emulsion layers. There is also a trend toward higher coating speeds (30 – 250 m/min) and greater support widths (1 – 2 m). For reasons of economy, the number of passes must be kept as small as possible; thus it is necessary to apply many coatings in a single pass through the coating machine.

Operation in Darkness. As photographic sensitivity increases and emulsions are sensitized far into the red portion of the spectrum, not even red light can be permitted during processing. Materials are therefore manufactured in the dark by using infrared light for automatic quality control and image converters for visual surveillance. When there are gaps in the spectral sensitivity of a material, light of a definite wavelength can be used.

3.3.1. Coating Machinery

The coating on the emulsion support consists of light-sensitive layers, which have an enormous range of photographic properties, and a number of auxiliary layers, which together or separately perform the following functions: light filtration, separation of differently sensitized emulsions containing different dye couplers (see Section 5.2.2.3), antihalation, mechanical protection, noncurl, subbing, antistatic, hardening, matt finish, and many others (see Section 3.2.1). The number of layers is steadily increasing, especially in color materials, because of more and more stringent requirements; at present, 10 to 15 is common. Generally these coatings are on one side of the material. Certain materials, however, such as X-ray films, have coatings on both front and back.

The coatings are usually applied in the form of an aqueous gelatin solution, dispersion, emulsion, or suspension; in some cases, solutions in organic solvents are employed. The coating material must be prepared before application; this stage may include melting, tempering, and the addition of "finals" to adjust surface tensions and viscosities, degassing, and filtration. The emulsion can be prepared batchwise or continuously. The design and sizing of the tanks and metering equipment depend initially on the lot size and secondly on the shelf life of the photographic emulsion, including finals.

Equipment for the *coating of long film or paper webs* (1 – 2 m wide and up to 5000 m long) includes devices similar to those employed in the paper converting or printing industry. Special machinery is used for the coating of plates made of glass or other materials, for example of optical filters, of photographic plates for scientific purposes, or of plates serving as the initial stage in the manufacture of printed circuits (→ Imaging Technology, Chap. 4.2.) and microelectronic devices (→ Imaging Technology, Chap. 4.3.).

A coating machine for film or paper webs is shown in Figure 34. The most important features include: the unwinding section (a) (usually there are two or even three unwinding stations in order to allow continuous operation); the device for splicing the webs (b); the web accumulator (c) which allow continuous running of the machine while, for example, a new web of material is being pasted to the old one or when a new web is begun at the windup station (h).

Modern machines with "flying attachment" to the new web do not have an accumulator ahead of the windup station; cleaning and pretreatment devices (d), such as a station for corona treatment to improve adhesion to resin-coated papers; the coating station (e); the emulsion feed tanks (f); the chilling and drying section (g); and the windup station (h).

Other components of a coating machine include equipment for the conveying, cooling, moistening, and cutting of the papers or films, dry air preparation, solvent recovery, and process measurement and control. Because of the large number of variables that must be determined and set, process-control computers are now used in large coating machines.

3.3.2. Coating Methods

Warm gelatin solutions (ca. 40 °C) can be applied by various methods (see Fig. 35 and [247]). All the coating systems have the following common features: they must produce a defect-free coating with a well-defined thickness that is highly uniform over the length and width of the web; they must be easy to operate and keep clean; and must offer high reliability.

Dip Coating. In the earliest process, dip coating (Fig. 35 A), the thickness of the coating applied depends on the speed of the web of material being coated, the viscosity and density of the coating solution, and the surface tension (web – coating solution). These quantities determine the quantity of liquid that the support picks up and carriers along against gravity and the quantity that runs back into the tank. In general, dip coating permits speeds of only 5 – 20 m/min. For a mathematical physics treatment of coating formation, see [30], [248][249][250][251][252][253][254].

Air Knife. In this process (Fig. 35 B) [255–258], excess coating material is removed with the help of a slot-shaped air nozzle; the nominal coating thickness is controlled by the intensity of the air blast. Emulsions coated by this method can have higher concentrations than in dip coating; as a result, drying capacity can be reduced or coating speed can be increased.

Roller Coater. Coating with pickup rolls (Fig. 35 C) is subject to conditions similar to those in dip coating (Fig. 35 A), but the coating thickness further depends on the spacing between pickup roll and emulsion support as well as the rotation speed and direction of the pickup roll. Higher coating speeds are possible with this process.

In the first three processes, the coating solution and the runoff must be recirculated to the coating tank in order to prevent concentration variations due to sedimentation and other factors. The remaining processes operate without solution return. The coating solution is precisely metered onto the support by way of measuring devices (capillaries, pumps). For this reason, the coating thickness does not depend on the viscos-

ity, but on three primary factors: metering rate, coating width, and speed of support.

Extrusion Coater [259], [260]. (Fig. 35 D). The uniformity of application across the web width depends strongly on the accuracy of the extruder die lips and the pressure distribution.

Slide Hopper Coater. The slide [261] (Fig. 35 E) and curtain coaters (Fig. 35 F) [253] can apply several coatings at once. The materials flow in superimposed layers down the cascade to the coating point. They do not mix because the flow is laminar. Metering devices convey the emulsions to the coating head; they flow in layers over the sloping top surfaces, form a "bead" (meniscus) at the point of contact with the moving support, and are stretched and picked up by the web of material. The wet thicknesses, viscosities, and surface tensions of the many emulsion layers must be suitably related to one another. The slide coating process is economic because it can produce multilayer coatings at high speeds (50 – 250 m/min) and it uses concentrated coating materials.

Curtain Coater. Curtain coating (Fig. 35 F) [253], [254], [262], [263], permits still higher speeds. Because of the wide spacing (20 – 200 mm) between the coating head and the emulsion support, it is possible to work past gaps or irregularly shaped supports without breaking up the curtain of falling material. The thin curtain must be specially protected, because it can very easily oscillate, which may cause process upsets and coating flaws. Lateral edge guides prevent the contraction of the falling curtain.

General. The coating systems described all require exact control of the *solution viscosity*. This can be achieved by varying the concentration, selecting the proper gelatin grades, adding other high-molecular-mass thickeners, or changing the temperature.

The *surface tension* is adjusted with wetting agents [252]. Alcohol is often used, but surface-active compounds such as saponins, potassium salts of acid alkenyl succinates, sodium salt of diisooctyl sulfosuccinate, salts of perfluorinated carboxylic acids, and other surfactants are also suitable for the purpose.

The operation is sometimes carried out at several coating stations, and thus possibly with a variety of coating equipment. In these cases, the layers first applied must be dried (setting may be sufficient) before the support comes to the next coating station, and so forth. If the coatings are not dry, the coating side must not be mechanically contacted.

Coating thickness is measured by radiography in a nondestructive manner during the coating step. The measured value can then be used to control the operation. The radiation dose involved is so low that it produces no developable blackening of the photographic material.

3.3.3. Chilling and Drying

The emulsion support with the gelatin solutions, applied warm, is conveyed from the coating station into the chilling zone, where the emulsions are soldified, often with the aid of cold, dry air (5 – 15 °C).

The geometry of the chilling section and the quantity and velocity of the cooling air must be selected to meet two criteria: Maximum heat transfer must take place, but the coating must not be damaged by the air blast. In order to maintain the coatings in a uniform state, it is crucial that they be transformed from a liquid state to a nonflowing state as quickly as possible. The capability of modern coating machinery to work with more highly concentrated solutions, dispersions, and the like is again an advantage, because these solutions set faster. Water is removed from the solidified emulsion in the downstream drying step. The time dependences of the emulsion temperature and moisture content, which are controlled through the parameters of the drying air, have a substantial effect on the photographic and mechanical properties of the photographic material.

On cooling, gelatin solutions go from the sol form – in which gelatin molecules are randomly distributed in the solution – to the gel form, in which the gelatin molecules take up a partly crystalline configuration [264]. This change usually takes more than two minutes and requires temperatures under 30 °C. The gel state has, for example, markedly better mechanical (e.g., lower brittleness), hardening, and swelling properties.

Drying involves two main steps [265–267]. In the first, water evaporates from the gelatin solution as from a free water surface. This first, physical drying step comes to an end when the gelatin concentration in the aqueous solution reaches ca. 30 wt %. In the next step, the evapo-ration rate is limited by diffusion of water (or other solvent) through the coating.

The temperature of the coating during the first drying stage is equal to the wet-bulb temperature of the drying air; in the second stage, when the surface of the coating becomes dry, it can reach the same temperature as the air.

When drying is complete, the photographic materials are carefully brought to predetermined moisture and temperature values in order to prevent static discharges during later operations or during use.

The cleanliness of the drying air is very important. Purification to remove gaseous impurities, such as hydrogen sulfide, nitrogen oxides, and ozone, is necessary, as is dust removal.

As in industrial climate-control systems, *moisture* is removed from the drying air by one of two methods: freezing followed by temperature adjustment, or with lithium chloride absorbers.

The moisture content of the traveling web of material in the several drying zones is often measured by IR absorption [268]. The *temperature* of the emulsion layer during the drying operation is also measured in a contactless manner, for example with pyrometers.

Increasing travel speeds and dryer capacities and the trend toward contactless conveying have led to drastic changes in the engineering design of the drying section. Film and paper webs were formerly conveyed slowly through the drying zones in festoons supported by recirculating pins, or drying wheels were used where the dryer length was restricted. Today, vertical or horizontal flat-layer dryers, several 100 m in length, some designed as floater dryers, are used. The drying air is blown onto the web through plates provided with round holes or slot-type nozzles.

Once the final coating and drying operation is done, the material is subjected to final inspection, put in temporary storage (as required for the specific product), and converted to salable form. The finished product is then obtained by cutting, stamping, winding, cementing, printing, packaging, and other operations.

3.4. Packaging

The term packaging here refers to all the operations carried out after the stock is coated in order to get the product ready for sale.

Film. Film is either cut into sheets or made into a wide variety of roll films. *Sheet film* [269], used chiefly by professional photographers, holds only a small share of the market. Cutting is performed with oscillating cutters or with single strip cross cutters working on film that has already been slit and wound. Notches are cut on the right hand side in the top edge of each sheet to identify the emulsion side and film type. Paper – aluminum – polyethylene composite film (Paalpo) is used for light-tight, climate-proof packaging.

Other than disk film [270], all films for amateur use are packaged in *roll form*. The most common sizes are 120, 220 [271], 135 [272], [273], 126 [274], and 110 [275] roll film. The sequence indicates the order in which these systems were devised. The Super-8 system of amateur motion-picture film now plays only a marginal role, because of the development of video technology. After some initial successes for the 126 and 110 systems the 135 system has achieved market dominance (more than 2×10^9 units per year worldwide). The manufacture of 135 films involves the following steps:

1) Production of film magazines
2) Slitting of film to 35 mm width
3) Perforating
4) Edge-mark printing
5) Loading of film into the film magazine
6) Packaging in plastic can or film, cardboard box, and shipping box

Modern high-performance equipment links these operations in a single series. Information in the edgeprint typically includes the frame number, the film type, the lot number, and even the image frame marks (126 and 110 sizes). Machine-readable barcodes, such as the DX code [273] and the frame number in coded form, have also been included. To edge-print the frame numbers with DX code, the film is brought into contact with specially prepared stencils and exposed. Edgeprints (e.g., film type and lot number) recurring at regular intervals and that are

independent of the film length are applied with egdge-printing drums. The film passes over the rotating drum, which has a light source inside it and a stencil between the light source and the film. Slides with a wide variety of characters make it possible to change film type or lot number information quickly. New edge-printing devices employ a matrix arrangement of many individual small light sources [276], which are illuminated by a control system in such a way that the desired message, consisting of single pixels, is imprinted on the film. The on-time of the individual light sources is only a few microseconds, so that the film can be imprinted on the fly. This type of edge-printing is freely programmable and thus very flexible, and it permits extremely short changeover times.

There are two fundamentally different ways of *loading film into magazines*. The most widely used is to wind the film on the spool outside the magazine, insert the spool and film into a magazine shell that has only one cap in place, and finally close the magazine with the other cap. In another technique [277], the magazine has two caps and the spool for the film, and the film is fed in through the magazine slot. This method can be used only with hook spools [278].

Photographic Paper. Photographic paper is also cut into sheets or slit and wound into rolls. Virtually all black-and-white papers are packaged in sheet form; color papers usually in the roll form.

As in the case of film, oscillating cutters are most often used for cutting the photographic paper into sheets. These machines have a high output (ca. 200 cuts per minute) and offer good cut quality. The single sheets are stacked (usually 10, 25, 50, or 100 sheets), enclosed in light-tight, climate-proof polyethylene or Paalpo pouches, and finally packaged in cardboard sleeves or boxes with identifying labels. Because of the huge number of possible combinations of format [279], gradation, surface finish, and number of sheets, there is a wide variety of stock items in sheet paper.

The preparation and packaging of photographic papers centers on color paper in roll form [280]. Most equipment used for this purpose is highly automated and very productive. High-performance roll slitting machines have an individual windup station for each paper strip. This design feature makes it possible to automate the entire operation, including the following steps: cut off when roll length is reached; remove rolls and convey to packaging; deliver, insert, and clamp new cores; and start winding strip on core. Using belt wrappers no glue or tape is needed [281]. The operations listed above are usually performed with the machinery stopped, but in modern systems they require only a few seconds. Travel speeds of 200 m/min and higher are common. All slitting operations are done with circular knives. Regular regrinding of the blades is vital if dust-free cutting and high edge quality are to be maintained. The top and bottom knife shafts are therefore integrated into a unit that can be changed out all at once; in this way, downtime for knife changing is kept extremely short, and maintenance and precise adjustment of the knives is simplified. Special equipment has been developed for splicing the photographic paper and then for punching long holes to mark the splices [282], [283]. Roll papers are usually packed in light-tight, climate-proof pouches made, for example, of Paalpo and kraft paper. Automatic horizontal bag forming – filling – sealing machines (e.g., those made by Omori, Japan) are used; bag materials are fed from rolls. The machines have adjusting motors so that they can be reset with a change in roll size. All the subsequent packaging and handling operations, up to the stage where the product is on pallets ready to ship, are also fully automated.

4. Black-and-White Photography

[284]

4.1. Negative – Positive Processes

Black-and-white (B & W) films are generally made with a cellulose triacetate support; PETP is used only for sheet films. Packaging and sizes are the same as for color films.

The structure of B & W films consists of one or two emulsion layers and protective overcoat, which may contain matting agents and friction-control substances.

Along with stabilizers, the *emulsion layers* may contain development accelerators, such as ionic surfactants based on poly(alkylene oxides) or quaternary salts of $C_{11} - C_{16}$ amines, for example laurylpyridinium bromide.

Some films, such as Agfa APX-25 and APX-100, have an *antihalation coating* between the emulsion support and the emulsion. These coatings must be completely decolorized in processing (by the action of the sulfite or of the alkali in the developer).

Roll and sheet films have an *NC coating* on the back. In general, this coating is dyed for antihalation protection and must satisfy the same bleachability requirements as the antihalation coating. APX-25 and APX-100 both have a separate antihalation coating and a dyed NC coating and thus exhibit excellent protection against halation.

The base for miniature films is dope-dyed gray and has a neutral density of 0.24. In many products, this dye is the sole provision against halation; it also prevents light piping (see Section 3.2.1.2).

Some B & W films are also *hardened* with formaldehyde; hardening in these materials continues for one to three years and results in sensitometric changes. The one-time hardening sometimes practiced does not have this drawback.

The gradation of B & W films can be varied over a wide range through the development time. Sensitivity and gradation also depend strongly on the developer composition. The manufacturers deal with this fact by publishing curves of gamma versus development time (for a definition of gamma see Section 6.1.2). For subjects having average contrast, the desired value is $\gamma = 0.65$. Densitometric measurements of B & W films are performed with diffuse light so as to eliminate the Callier effect, which leads to an increase in density as a function of the specularity of the light used for measurement.

Prolongation of the development time always makes the characteristic curve steeper and increases the sensitivity, since small latent-image centers become developable. Special methods of attaining maximal sensitivity are based on limiting the increase in steepness (retarded development; see Section 4.3.2).

The *"zone system"* was devised by A. Adams. Its basic principle is matching of the gradation of the negative to the subject contrast as measured with a spot exposure meter. Since development time differs from picture to picture, depending on subject contrast, the process can be used only with sheet film. When the resulting negatives are enlarged and printed on grade 2 paper, the prints show both deep shadow and detail in the highlights.

Excellent edge sharpness, resulting from adjacency effects (see Section 2.3.4.2), is achieved when technical films, which have $\gamma = 1.5 - 2.0$ in normal processing, are developed to a pictorial gamma value of ca. 0.65. Examples of such materials are Kodak Technical Pan 2415 and Agfa-Gevaert A O – 25. Development is carried out in Phenidone – sulfite or in highly diluted standard developer. All such processes with "restrained" development are susceptible to development fog, because convection at the film surface strongly influences the quantity of silver developed out.

In general, B & W films are *panchromatically sensitized*, with a range of ca. 400 – 640 nm. Special materials offer sensitivity at longer wavelengths, up to 690 nm (Technical Pan) and 740 nm (AP-200 S). The advantage of this sensitization is the high sensitivity when a red filter is used; the disadvantage is that some tones, such as red lips, are reproduced too pale. Under the heading of special materials, Kodak High Speed Infrared 4143 deserves mention. This film is sensitive to 900 nm and even behind IR filters, which appear black to the eye.

The transformation from colors to gray-scale values always has an element of arbitrariness. Well-defined standard colors are reproduced with different values by different products. The tool for comparison is the color step wedge, in which colored surfaces (yellow, blue, green, red) are each combined with a gray wedge.

In general, blue becomes lighter as the film sensitivity increases, since the volume sensitivity (intrinsically blue) increases more rapidly with grain diameter than does the sensitized sensitivity, which is proportional to the surface area. As a consequence, the sensitivity of high-speed films declines markedly in incandescent light, which contains less blue.

The gray values can be controlled in any desired way with filters used at exposure time. Yellow, orange, or red filters are most often used to cause blue sky to appear dark. Red filters give the impression of clearing haze, since long-wavelength light is scattered least on aerosol particles. These filters are frequently used in aerial photography. Aerial survey films are therefore sensitized in the long-wavelength red. Filters for

B & W are much more strongly colored than the correction filters used in color photography.

Figure 36 presents typical density curves for optimally ripened emulsions that differ in grain size but have the same coating weight. As the grain size increases, the sensitivity increases while the maximum density decreases. This behavior reflects the fact that the covering power is strongly dependent on the morphology of the developed silver. One compact grain absorbs less light than a number of small grains having the same total volume. Thus the Lambert – Beer law does not apply.

Figure 36. Sensitometric curves of different emulsions after B & W development; coating weight is 3 g silver per square meter for each emulsion
a) Mean diameter 1.2 µm; b) Mean diameter 0.7 µm; c) Mean diameter 0.3 µm

According to SIEDENTOPF and NUTTING, the granularity σ_D also increases with grain size (for a definition of granularity, see Section 6.2). The ratio of sensitivity to granularity is a measure of the efficiency of the photographic primary process and characterizes the quality of emulsion.

Since a maximum density of 3.0 is completely sufficient for pictorial photography, low-speed films can have a lower coating weight than high-speed ones. Typical values are 3 – 4 g $AgNO_3$ per square meter for ISO 25/15° films, 6 g for ISO 100/21°, and 9 g for the ISO 400/27° class.

The loss of sharpness with increasing sensitivity results from the heavier coating weight and, in practice, limits the coating weight. Higher sensitivity is thus achieved at the cost of signal to noise ratio, as in other detection systems. This situation has nothing to do with the quantum nature of visible light, for the "quantum noise" is far less than the granularity of ordinary B & W films. In contrast, the quantum nature of the radiation plays a role in producing the granular structure in X-ray films.

In all conventional B & W films, the granularity σ_D increases with the negative density D. The rise in σ_D is usually less than predicted by the Siedentopf relation $\sigma_D \sim \sqrt{D}$, because at higher densities even the smaller emulsion grains contribute to the image. The practical consequence is a fundamental rule of B & W photography: i.e., use the least exposure possible.

Overexposure also works to the detriment of sharpness. This effect depends on the type of developer because the image silver is unevenly distributed in the emulsion layer. At low densities, it is more highly concentrated at the film surface than near the emulsion support. Near the support scattering on silver halide grains has the greatest effect of reducing the light modulation. Special techniques for achieving maximum sharpness, namely the use of "surface developers," tend to produce the image chiefly at the grain surface. This principle always has the drawback that the characteristic curve departs from that for standard development, since higher densities cannot be formed without the grains in the bulk of the emulsion.

Three sensitivity classes have been established in B & W photography:

1) The ISO 25/15° class offers the least granularity and the greatest sharpness; Agfa APX-25 is an example. Such films are used when a stand is available; for example, to reproduce continuous tone images or in architectural photography.
2) The ISO 100/21° class permits the use of a handheld camera in normal sunlight and is therefore the most frequently used.
3) The ISO 400/27° class finds use not only with poor lighting, but also for subjects in motion, as in sports photography. These films are the standard materials of press photographers.

T-Max Films. Tabular emulsion grains, in comparison with those of a more spherical form, offer higher silver covering power as well as lower light scattering, provided the long axes of

the T-grains can be oriented parallel to the film plane. Kodak T-Max P3200 has a high-speed layer containing crystals with a lateral diameter of 5 – 6 µm and a thickness of ca. 0.2 µm (aspect ratio around 20 – 30). The material has a speed of ISO 1000/31° and a sharpness comparable to that of the ISO 400/27 °C class (see Fig. 37).

Chromogenic B & W Films. In 1980, Ilford and Agfa simultaneously presented B & W films (Ilford XP-1400 and Agfa Vario XL) that produced a monochrome, approximately gray negative in chromogenic development. The gradation of these films, when developeed by the standard process for color negative films, is ca. $\gamma = 0.90$.

The departure from the normal gamma value of 0.65 for conventional B & W films is due to the absence of the Callier effect in chromogenic films, which produces an increase in effective gradation on enlargement with certain types of light source. The advantage of color processing is that it is widely available and the conditions are generally precisely controlled. The user sacrifices some creativity in extending latitude of development, but gains better reproducibility of speed and gamma.

The decisive factor is that the granularity σ_D of chromogenic films decreases on overexposure, in contrast to conventional B & W materials (see Fig. 38). The shape of the granularity versus density curve is a general property of modern color negative materials containing DIR couplers. The reasons are DIR action (see Section 5.2.2.5) and double-coating.

Chromogenic B & W materials have dye couplers for cyan, magenta, and yellow, as well as DIR couplers, in two panchromatic emulsion layers. The higher-speed emulsion layer has a markedly lower content of dye couplers (relative to the silver content) than the lower-speed layer (double- coating principle). In all other details, the films are identical with conventional color negative materials.

Because of the lower content of dye couplers, all dye coupler available in the layer is coupled from a certain exposure value on and the statistical grain distribution of the high-speed layer is not imaged as a density variation. This configuration corresponds to a detection system whose sensitivity is matched to the signal intensity.

Figure 37. Electron micrographs of conventional ISO 400-B & W film (top) and Kodak T-Max P 3200 containing tubular grain emulsion (bottom)

A chromogenic B & W film with a speed of ISO 400/27°, exposed as if it were ISO 100/21°, gives images with significantly finer grain than the same film normally exposed, thus attaining the image quality of an ISO 100/21° B & W film.

4.2. Reversal Processes

Kodak and Agfa currently offer films specially designed for *B & W reversal processing* (see Section 4.3.3.7). The speeds are ISO 16/13° (Agfa – Gevaert Dia Direct) and ISO 100/21° (Kodak Direct Positive Panchromatic Film 5246). In principle, any B & W film can be developed by a reversal process; the quantity of silver halide solvents in the first developer must simply be matched to the film type.

Direct positive-working films, which give a positive image in normal developer, have speeds roughly equal to those of B & W paper and are suitable for reprographic applications (Kodak B/W Duplicating Film 4168).

Figure 38. Typical plot of granularity vs. optical density for chromogenic (a) and conventional B & W films (b) of equal speed

4.3. Processing of Exposed Black-and-White Materials

Two types of development, chemical and physical, are distinguished (see Section 2.3.1). These historical names are not wholly correct and may be misleading. The chemical processes involved in them cannot always be sharply separated.

In its purest form, *physical development* takes place in the development of prefixed silver halide layers. The exposed emulsion is treated in a solution of sodium thiosulfate (hypo) containing silver bromide, until all the silver halide has dissolved and only the photolytically formed silver centers remain in the layer. After an intermediate treatment with a sodium sulfite solution, the layer is developed in a solution of Metol (**44**, see Section 4.3.1.2) and sodium sulfite, which contains a dissolved silver sulfite complex. At the sites where nuclei of photolytically formed silver are located, the silver sulfite complex is reduced to metallic silver [285].

Physical development is mainly of theoretical interest, although underdeveloped negatives can sometimes be intensified by subsequent physical development. Physical development is important as a subsidiary process to normal "chemical" development and occurs in developers that contain sufficient amounts of silver halide solvents, such as sodium sulfite.

4.3.1. Developing Agents

There are many reducing agents for silver halides, but only a few can be used as developing agents [11, vol. 2, pp. 813 – 926]. Developers must be capable of reducing only those silver halide grains that contain a latent-image center produced by exposure. Silver halide crystals having no latent-image center but containing fog nuclei or no image centers at all must be reduced very slowly or not at all. In order to attain this goal, two basic criteria must be met: (1) The *kinetic condition* is that crystals with latent-image centers must be developed (under the catalytic action of the centers) orders of magnitude faster than crystals having no latent-image centers. (2) The *thermodynamic condition* for development is that the potential of the developing redox system must be more negative than the Ag^+/Ag potential. Only in this way can a photographic material be developed to form an image.

Developing agents can be inorganic or organic, but only organic substances are of any practical value.

4.3.1.1. Inorganic Developing Agents

In 1877 C. Lea discovered the developing action of potassium dioxalatoferrate(II),

$K_2[Fe(C_2O_4)_2] \cdot 2\,H_2O$. This developer was frequently used in the past, but today it is merely of historical interest, along with the salts and complex salts of chromium, molybdenum, tungsten, uranium, copper, and titanium. Their loss of importance is due to their low activity, rapid exhaustion, and poor stability of the developer solution. The vanadium(II) developer first described in 1894 by A. and L. LUMIÈRE can be electrochemically reduced and continuously regenerated; it was proposed for the development of motion-picture film because of its very rapid action [286]. It has not come into widespread use because development is only possible in hydrogen bromide solutions which are highly corrosive.

A second group of inorganic developers, which are mainly of theoretical interest and useful at best for the development of special-purpose emulsions, contain as developing agents sulfite, reductants based on sulfinic acid derivatives, (marketed, for example, as Rongalit by BASF), hydrogen peroxide in alkaline solution, hydroxylamine, or hydrazine.

4.3.1.2. Organic Developing Agents

Organic developing agents possess hydroxyl or amino groups. Their general constitutional formula was published by LUMIÈRE and SEYEWETZ in 1891 and ANDRESEN in 1892 and expanded later by KENDALL and PELZ. The most general form is [287]:

$$Y\text{-}(A{=}B\text{-})_n\,Y'$$

where Y and Y′ an represent OH, NH_2, NHR, or NR_2 groups.

Most developing agents can be placed in one of the following four groups.

1) $n = 0$: hydrogen peroxide, hydroxylamine, hydrazine (see Section 4.3.1.1)
2) $n = 1$, A = B = carbon: ascorbic acid, catechol, pyrogallol, 2-aminophenol, *o*-phenylenediamine and its substitution products, and 4-amino-1-phenyl-5-pyrazolone derivatives.
3) $n = 2$, A = B = carbon: hydroquinone (**43**), 4-aminophenol, *N*-methyl-4-aminophenol (**44**), and *p*-phenylenediamine and its derivatives.
4) $n = 1$, A = carbon, B = nitrogen: 1-phenyl-3-pyrazolidone (**45**) and 1-(*p*-aminophenyl)-3-amino-2-pyrazoline.

The most important of these compounds for B & W photography are hydroquinone (**43**); N-methyl-4-aminophenol, whose hydrogensulfate (**44**) is known under the trade names Metol (Agfa) and Elon (Kodak); and 1-phenyl-3-pyrazolidone (Phenidone, **45**) and its derivatives.

The development of exposed silver halide by hydroquinone can be represented as

The reaction with Phenidone is

and the general reaction is

$$\text{Red} + 2\,\text{AgX} + 2\,\text{OH}^- \xrightarrow{\text{Ag}_n} \text{Ox} + 2\,\text{Ag} + 2\,\text{X}^- + 2\,\text{H}_2\text{O}$$

Black silver metal, or image silver, is produced from the nearly colorless silver halide. From the reduced form of the developer (Red), its oxidized form (Ox) is generated. In color de-

velopment, the oxidized form of the developer is responsible for the color, but in B & W development these oxidation products play no role. It has been suggested that the oxidation products of B & W developers can be used to intensify the silver image through intermolecular or intramolecular dye formation; one purpose of doing this would be to save silver [288].

Hydroquinone, one of the earliest B & W developers, is still important (→ Hydroquinone, Chap. 7. In high-contrast special-purpose developers, hydroquinone alone is used at a high pH. It is a principal ingredient, with Metol (**44**) or with Phenidone (**45**), in most B & W developers, where it has a superadditive effect (see below).

Catechol (1,2-dihydroxybenzene; → Phenol Derivatives, Chap. 2.) is employed in sulfite-free tanning developers, which not only reduce the silver halide but also (by means of catechol oxidation products) tan the unhardened gelatin in regions where development has taken place, thus rendering it insoluble.

N-Methyl-4-aminophenol sulfate (Metol) (**44**) was introduced by A. Bogisch in 1893 in the form of Metol – hydroquinone developer. It has lost much of its earlier importance to Phenidone. Metol is used by itself in soft-working developers. In combination with hydroquinone, it was commonly used for decades as a powerful, fast-working developer. Because it allowed development even in acidic media, it was used to initiate acidic physical development.

4-Aminophenol in strongly alkaline solution is employed as a one-time developer for amateur B & W films (tradename: Rodinal).

Developers containing 4-hydroxyphenylglycine (called glycin developers) have not retained their former importance, nor have the slow-working but fog-free Amidol developers (containing 2,4-diaminophenol) although the latter are still employed for nuclear track emulsions.

Phenidone (**45**) (1-phenyl-3-pyrazolidone) was discovered in 1940 [289]. It is the only heterocyclic compound that has achieved great value as a developer. It exhibits a very strong superadditive effect with hydroquinone, so that it can be used in small quantities. In comparison with Metol, Phenidone has the advantage that its primary oxidation product, a radical, does not react with sulfite and thus is not withdrawn from the development cycle. Phenidone has the disadvantage of being sensitive to hydrolysis in alkaline media. Derivatives of Phenidone that are mono- or disubstituted at the 4-position are, however, resistant to hydrolysis.

The phenimines, or substituted 1-phenylpyrazoline derivatives, have an amino group at the 3 position (**46**). They include developing agents that show a very strong superadditive effect with hydroquinone. In comparison with Phenidone, they have the advantage of short latency periods [290]. Developing agents taken from the class of 3-alkyl-4-amino-1-phenyl-5-pyrazolones (**47**) have proven useful in automated developing equipment that must handle a variety of emulsion, because these developers are relatively insensitive to variations in the bromide content. They have also been proposed for the development of nuclear track emulsions [291], [292], [293]. Neither of these types of developing agents has acquired any market importance.

46 **47**

Heterocyclic developers containing oxygen include ascorbic acid (vitamin C) as well as the structurally similar hydroxytetronic acid and its imide [294]. These substances, whose oxidation products are colorless, are mixed with Metol or Phenidone to obtain special-purpose developers. For example, sulfite-free Metol – ascorbic acid developers are employed when only the latent image on the surface of the silver halide grain is to be developed.

Superadditivity. If an exposed silver halide emulsion is developed more strongly by a combination of two developing agents than the sum of the developments by the agents singly, this effect is called superadditivity. For decades the most important developer pair with superadditivity was Metol and hydroquinone, but this combination has been replaced by the even more strongly superadditive pair Phenidone and hydroquinone.

This effect is accounted for by a regeneration process or the removal of the charge barrier. The nitrogen- containing developing agent, Metol or Phenidone, is preferentially adsorbed by silver metal and silver halide. In exposed regions of the halide, the developing agent is oxidized to a radical while silver halide is reduced to silver metal. In this way the latent-image center becomes larger.

One explanation for the superadditive effect is that the radical adsorbed to the silver halide grain is reduced to the original developer molecule by the hydroquinone dianion, so that development can take place again (*regeneration process*).

But it is also conceivable that the increase in the size of the latent-image center locally breaks down a charge barrier at the surface of the silver halide grain, making it easier for the hydroquinone dianion to reach the crystal surface and thus promoting development by hydroquinone [295].

In the most recent theory, both reaction mechanisms occur in the Phenidone – hydroquinone pair. At high pH and low Phenidone concentration, the elimination of the charge barrier would play the major role; at low pH (ca. 7 – 8), regeneration would dominate [295].

4.3.2. Developer Solutions

The term "developer" generally denotes an aqueous solution containing all the substances needed for the development of a photographic material. The essential constituents of developer solutions are the developing agent proper and a variety of buffers and protective substances.

Photographic emulsions exist that already contain developing agents. The reason why this presents no difficulty is that most developing agents reduce exposed silver halide only when in an alkaline medium. These emulsions are made weakly acidic and thus cannot be reduced. Such emulsion layers are stable and must simply be placed in an aqueous alkali solution for development. Development begins as soon as the developing agent dissolves in the inward-permeating alkaline solution. The process has the advantages that development takes place very rapidly and the material cannot be overdeveloped.

4.3.2.1. Developer Formulas

A great number of developer formulas are known; often they differ in only small ways. For example, all manufacturers of photographic materials formerly published the formulas they considered best. Different formulas are naturally suggested for different intended results and processing conditions. While development used to take place only in trays and in tanks at temperatures of ca. 20 °C, processing temperatures have now risen (to 50 °C) and automated devices and machines have become more important.

In order to save labor and achieve constant results, premixed processing chemicals are preferred. Their compositions are often trade secrets, but environmental and occupational-safety regulations now force the disclosure of the composition of several of these premixed chemicals. Such premixed chemicals often contain additives comprising an improvement or technical advance not embodied in the corresponding published formulas.

4.3.2.2. Developer Additives

Besides developing agents proper, developers contain other ingredients to perform a variety of functions.

Buffers. The great majority of developing agents work only at pH > 9. Only in a few special cases is a pH of 7 – 8 high enough. Developers therefore contain bases, especially sodium and potassium carbonates but also borates, phosphates, sulfites, and sodium and potassium hydroxides. Nitrogenous bases can be used only if they have a low dissolving power for silver halides, since otherwise the emulsion will be fogged during development; triethanolamine is an example for a base with low dissolving power. Hydrogen halide is liberated in the development process, and so the buffering capacity of the developer solution must be high enough to keep the pH from dropping. Developers with high hydroquinone concentrations can even be used with an alkali hydroxide alone, since the hydroquinone dianion provides adequate buffering in the pH range from 10 to 12.

Preservatives. Being strong reducing agents, developing agents are very sensitive to oxygen, especially in alkaline solution. The addition of antioxidants is therefore essential in practice. A particularly good choice is sulfite. In the presence of hydroquinone, sulfite reacts with oxygen to form hydroquinonesulfonic acid, sulfate, and hydroxide. In this way, the formation of colored oxidation products of the developing agents is prevented even under incorrect processing conditions. In addition, the capacity of sulfite to dissolve silver halide often results in a desirable effect; i.e., promoting physical development and yielding a fine, compact silver grain. In fine-grain developers containing Amidol or Metol as developing agent, sulfite actually performs three functions: buffer (pH 7–8), preservative, and silver halide solvent helping to refine the grain structure. In direct positive emulsions where the sensitivity centers are inside the silver halide crystals grains (see Section 2.4.3), sulfite facilitates internal development, because it dissolves the outer, undeveloped layers of the silver halide crystal and releases the latent-image centers lying inside so that development can then take place on them. A developer without a solvent for silver halide cannot develop such special-purpose emulsions.

Restrainers. Photographic fog arises when unexposed silver halide is developed. The nonimage silver formed lowers the transparency in films or degrades the highlights in prints. Fog results from a variety of causes and therefore must be combatted in a variety of ways.

Excessive ripening or sensitization of the emulsion can generate silver halide crystals that are developable without exposure (ripening fog, sensitization fog). When the activity of a developer is increased by raising its concentration, the pH, or the temperature, even unexposed silver halide grains are developed. The higher the capacity of the developer to dissolve silver halide (e.g., due to sulfite, thiosulfate, ammonia, and similar agents), the more fog it will produce by physical development on the fog nuclei. The action of atmospheric oxygen on the developer can lead to the formation of hydrogen peroxide or its derivatives when trace heavy metals are present. The same process can initiate the development of unexposed silver halide.

The most important restrainers are sodium and potassium bromides. A number of organic substances (antifoggants) are also used; these include benzotriazole, benzimidazole, and phenylmercaptotetrazole. All these agents form sparingly soluble silver compounds and are strongly adsorbed to the surface of the silver halide grains. Presumably, they stop fogging by retarding physical development, whether through their adsorption to the grain surface (which inactivates the fog nuclei) or because they reduce the concentration of complexed silver in dissolved form. At the same time, however, these additives restrain development, and so the concentration of antifoggants in the developer should be held low and as constant as possible.

The restraining action of some dyes (phenosafranine, pinakryptol green) and some anthraquinone derivatives might be attributed to a direct or indirect redox reaction with the agent that causes fogging.

Water Softeners. Since deionized water is seldom available for preparation of the developer, a sequestrant must be added. In the alkaline developer solution, the magnesium and calcium salts from tap water form insoluble precipitates, which vary in composition and character (hydroxides, carbonates, sulfites, sulfates, borates, phosphates). Floccular precipitates are less of a problem than those that form incrustations. Incrustations occur especially in developing machines, plugging water lines or impairing heat exchange and thus interfering with the proper functioning of the equipment. Such precipitates can also scratch the photographic material.

Suitable sequestrants are both inorganic and organic substances that form highly water-soluble complexes with magnesium and calcium ions. The inorganic compounds include polymetaphosphates (e.g., Calgon) and polyorthophosphates. They have the disadvantage that they slowly hydrolyze to orthophosphates at elevated temperatures, thus forming sparingly soluble salts. Organic sequestrants include hydroxycarboxylic acids, such as citric acid, and aminoacetic acid derivatives, such as nitrilotriacetic acid and ethylenediaminetetraacetic acid. The latter group is gaining importance. Organic phosphonic acids are not sequestrants in the proper sense; they do not prevent precipitation

but merely impede the formation of adherent crusts. They are used for masking iron ions.

Image-Tone Modifiers. The image tone of a B & W image depends on the form of the precipitated silver. The image tone can also be controlled with inorganic and organic developer additives. For example, the addition of a small amount of thiosulfate shifts the tone toward blue, producing a colder image tone. The same effect can be achieved with substituted thioureas and with heterocyclic thioketones; for example, 4-bromo-2,3-dimethyl-1-phenyl-5-thiopyrazo- lone, like thiosulfate, has the ability to dissolve silver halide. Benzotriazole can also produce a blue tone. With some emulsions, the addition of ternary sulfur compounds and quaternary compounds of nitrogen and phosphorus to the developer can shift the tone toward brown. These ternary and quaternary substances are much more effective when added to the emulsion and are therefore added before coating the support.

Development Accelerators. The induction period (see Section 2.3.3.1) can often be shortened, by the addition of quaternary nitrogen compounds, such as laurylpyridinium chloride, or of poly(ethylene oxides), so that development is accelerated.

Organic Solvents. For ease of use, developers are often sold in the form of concentrated solutions, which are simply diluted with water before use. Because organic developing agents are sparingly soluble in water, they are frequently dissolved in organic solvents such as ethylene glycol, diethylene glycol, or triethanolamine. These additives simply act as solvents and have no photographic effect. Triethanolamine, however, can also provide buffering in the developer solution (see page 65).

4.3.2.3. Special-Purpose Developers

Hardening Developers. When photographic materials are processed at higher temperatures (e.g., ca. 50 °C) it is often necessary to add gelatin-hardening (tanning) agents to the developer. Proven additives for this purpose include dialdehydes, such as succinaldehyde or glutaraldehyde, which offer a hardening action even in the presence of sulfite but do not react with developing agents and hence do not interfere with development.

Lith Developers. Developers with extremely high- contrast working are used for lithographic purposes. They must contain only very small amounts of free sulfite, since otherwise the desired lith effect is not produced. However, it is impossible to do without sulfite altogether, for the developer would then be too unstable and oxidation-sensitive. The problem is solved through the addition of sodium hydroxymethanesulfonate ("formaldehyde bisulfite," $HOCH_2-SO_3Na$), or a mixture of paraformaldehyde and sulfite, (which in solution give sodium hydroxymethanesulfonate), or sodium cyclohexanone bisulfite. In the alkaline developer solution, these compounds dissociate partly into sulfite and formaldehyde or cyclohexanone. The sulfite concentration is then high enough to provide adequate protection against atmospheric oxygen without interfering with the lith development (sulfite buffer).

Fixing Developers or "Monobaths." For special purposes, such as the rapid processing of X-ray, logging, aerial-survey films (for military aerial reconnaissance), or microfilm, fixing developers have been devised. Fixing developers contain enough silver halide solvent to remove the unexposed silver halide (fixation) during the ordinary development time. Development must be largely complete before fixation commences. Some loss of sensitivity and contrast is unavoidable. In order to restrain physical development, which would result in unacceptable fogging, such monobaths contain relatively high levels of bromide (up to 10 g/L).

In addition to sodium thiosulfate, aliphatic and heterocyclic thiols, can be used as fixers which form highly water-soluble silver complexes in the high-pH developer. Modern fixing developers also have additives that prevent or at least retard the formation of silver sludge. Because fixing development is very susceptible to problems and can be applied to only a few materials, it has not come into general use [296].

Paste Developers. Black-and-white developers can be thickened with methylcellulose, carboxymethylcellulose, or synthetic polymers. Such developers are said to give sharper images and much more consistent development than unthickened ones. Despite these advantages, the processing of photographic materials with thickened baths has not gained acceptance except in the processing of optical sound films (thickened sound-track developer, thickened bleach bath). The removal of the paste materials involves serious difficulties and high costs. Significant amounts of thickening agents must be added to the baths, so that the wastewater has a high suspended solids content and a high oxygen demand. Both factors play a role in wastewater treatment cost calculations. Suitable replenishment processes free of nonrecoverable pastes are unknown.

4.3.3. Postdevelopment Treatment

4.3.3.1. Stopping

Stop baths are used to break off the development process quickly and as uniformly as possible. With adequate replenishment, this bath also provides an intermediate wash, preventing large amounts of developer getting into the fixing bath, and thus preventing additional fog.

Acidic Stop Bath. A proven stop bath is 0.5 – 2 wt % aqueous acetic acid, which may also contain a gelatin-hardening agent such as formaldehyde or an aluminum salt (hardening stop bath). Development is cut off by the nearly instantaneous drop in pH in the emulsion layer upon addition of the stop bath.

Neutral Stop Bath. Development can also be stopped by quick fixation of the silver halide with a sodium or ammonium thiosulfate solution (stop – fixing bath). Thiosulfate solutions may also contain an aluminum salt for hardening (hardening stop – fixing bath).

4.3.3.2. Fixation

Undeveloped silver halide must be dissolved out of the photographic material, or it will continue to develop (darken) in light. Of the known solvents for silver halide, such as ammonia, thiourea, heterocyclic mercapto compounds, concentrated alkali halide solutions, cyanides, thiocyanates, and thiosulfate, the only ones of any importance in practice are sodium and ammonium thiosulfates. They must be used in fairly high concentrations, since only the thiosulfate-rich silver complexes $[Ag(S_2O_3)_2]^{3-}$ and $[Ag(S_2O_3)_3]^{5-}$ are readily soluble in water. *High-speed fixing baths* always contain ammonium salts, such as ammonium chloride or ammonium thiosulfate, because these baths dissolve the silver halide more rapidly than pure sodium thiosulfate solutions. Potassium thiosulfate cannot be employed because the complex salts it forms with silver are not easily soluble. Fixing baths contain sulfite to improve their stability. Acidic fixing baths contain sodium hydrogensulfite or an alkali disulfite such as potassium metabisulfite (potassium pyrosulfite, $K_2S_2O_5$). They can be used as stop baths, so that no intermediate stop bath is necessary, but the fixing bath must be adequately replenished. *Acidic fixing baths* may also contain aluminum salts such as potassium aluminum sulfate to harden the gelatin, as well as acetates and borates as complex-forming buffer compounds to prevent the precipitation of basic aluminum salts.

B & W papers that give a warm, brown-black image tone when dried at room temperature often have the disadvantage of turning an unattractive gray when dried on a hot glazing drum. To avert this color change ("burning"), heterocyclic mercapto compounds are added to the fixing bath. These are adsorbed to the silver metal and block the color change by preventing the individual silver grains from sintering together. The substances used for this purpose must not interfere with fixation.

The time required for fixing can easily be determined on transparent material. Generally speaking, fixation is complete as soon as the last fog due to silver halide has vanished from the emulsion layer. In the case of opaque materials, the unfixed silver halide can be detected only through intense exposure (photolysis) or by a chemical test in which silver sulfide is formed. Excessively long fixing should be avoided, since fine-grained precipitated silver is dissolved under the action of atmospheric oxygen, causing loss of detail (erosion of highlights).

4.3.3.3. Washing

Thorough washing after fixation is essential if stable B & W silver images are to be obtained. Since any silver thiosulfate complex not removed will gradually decompose to silver sulfide, the highlights will become fogged. (Insufficiently washed-out thiosulfate slowly disproportionates into sulfite and sulfur, and the sulfur oxidizes the image silver to form silver sulfide.) If this happens, a yellow-brown color will appear especially in regions of low image-silver density.

Most photographic papers have resin coatings on both sides of the base (see page 52). Because the processing solutions cannot penetrate into the fiber base, only a relatively short wash is needed.

In developing machines, papers are washed with running tap water; a countercurrent arrangement is used in order to save water. The rate of washing depends on the water temperature (increase in diffusion rate) and the thickness of the swollen emulsion layer (diffusion length). It is also influenced by the quality of the fixing bath, especially in the case of non-resin- coated papers. Acidic fixing baths cannot be washed out of the fiber base as quickly as neutral and, especially, as alkaline baths. When acid fixing is practiced, the papers should pass a soda bath before washing. The soda raises the pH in the emulsion layer and the support. A similar effect is achieved with a sulfite bath after fixation. Thiosulfate residues are destroyed by nonoxidizing substances that react with thiosulfate but do not attack the silver metal; an example is sodium chloroacetate [297]. Thiosulfate and sodium chloroacetate react to form the sodium salt of an *S*-ester of thiosulfuric acid, i.e., a Bunte salt:

$$^{-}O_3S-S^{-} + Cl-CH_2-COO^{-} \longrightarrow$$
$$^{-}O_3S-S-CH_2-COO^{-} + Cl^{-}$$

4.3.3.4. Stabilization

If the image need not meet archival standards but rapid access is needed, the time- consuming process of fixing and washing can be replaced by stabilization of the image. In this operation, only part of the undeveloped silver halide is dissolved; most of it remains as a silver compound having little light sensitivity. These compounds are formed with the components of the stabilizing bath that have penetrated into the emulsion. Acidic stabilizing baths contain thiosulfate, thiocyanate, thiourea, or organic sulfur compounds, such as thioglycolic acid (mercaptoacetic acid), thiosalicylic acid, or mercaptopyrimidine derivatives at relatively high levels.

To prevent yellowing of the silver image, stabilizing baths further contain small amounts of heterocyclic mercapto compounds, such as phenylmercaptotetrazole, which yield sparingly soluble silver compounds. To prevent the formation of colored oxidation products from residual developing agents in the emulsion, these baths also contain reducing agents such as sulfite or formaldehyde. After stabilization, the material should be washed no more than necessary; film materials should get only a very brief wash in order to dissolve salts present on the film surface that would otherwise crystallize and cloud the film. Provided the stabilized image has not become discolored, it can be converted to a form with ordinary stability by subsequent fixing and washing [298].

This *two-bath-process* (tradename Rapidoprint) has lost ground in favor of the standard process of development, fixing, and washing. High-speed developing machines using the conventional sequence of baths, working on B & W papers with incorporated developing agents, yield high-quality images in such a short time that the stabilization process now offers virtually no time advantage.

The term "stabilization" also includes processes by which *already processed B & W materials can be given archival stability*. The stability of the silver image is threatened not just by residual thiosulfate in the image but also by oxidizing gases, which convert the image silver to finely dispersed silver oxide. When this happens, the gray tone, chiefly in regions of low image density, changes to a yellow-brown. Hydrogen peroxide has particularly aggressive action; this gas is mainly evolved from new wood furniture and from the boards on which pictures are mounted. This harmful effect can be suppressed by treatment with a silver stabilization bath after washing. Agents that can be used for this pur-

pose include substances containing sulfur and nitrogen; for example, thiocyanates (tradename Sistan) and thiourea derivatives [299].

4.3.3.5. Reduction, Intensification

Reduction. Negatives that are too dense (as a result of overexposure) to be printed can be rendered copiable through subtractive reduction. In this process, the image silver is diminished by the same amount everywhere. The negative retains its original gradation. The silver is oxidized with a strong oxidizing agent, such as permanganate, dichromate, or persulfate, and then dissolved and removed. The best-known agent is Farmer's reducer, which consists of potassium hexacyanoferrate(III) and sodium thiosulfate.

Proportional reducers can be used to diminish negative contrast. These substances mainly attack the silver in regions of high density; regions of low coverage are only slightly attacked. In this way, the gradation is flattened without any loss of detail in the highlights.

Proportional reducers contain ammonium peroxodisulfate or the sodium salt of the iron (III) – ethylenediaminetetraacetate complex as oxidizing agent. The latter oxidizing agent has the advantage that it does not attack thiosulfates. It reacts with them to form stable reducers; in color photography, such reducers are widely used as bleach – fixing baths.

Intensification. Negatives that have been underexposed or underdeveloped and do not have sufficient coverage to give usable positives can be intensified by treatment with a physical developer or with mercury(II), copper(II), or uranyl salts. Depending on which process is employed, a metal or metal-salt image is superimposed on the silver image.

4.3.3.6. Toning

Many special papers, when normally developed, give silver images with a blue (cold), green, yellow, or brown (warm) tone instead of a neutral black image. It is also possible to convert an already processed B & W silver image subsequently to a colored or toned image.

Toning processes have the drawback that the resulting color tones depend strongly on the quality of the silver image and on the treatment it has received. Some toning processes require bleaching with potassium hexacyanoferrate(III) and potassium bromide. In sulfur toning, in which the bleached silver image is treated with sodium sulfide to produce a silver sulfide image, the tone ranges from yellow to brown, depending on the bromide content of the bleaching bath. Similarly, antimony toning with sodium antimony sulfide (Schlippe's salt, $Na_3SbS_4 \cdot 9\,H_2O$) gives brown to ocher- colored tones, and copper(II) hexacyanoferrate(III) toning gives violet-brown to cherry-red tones. Gold toning baths with gold(III) chloride and ammonium thiocyanate yield blue-black tones without intermediate bleaching; the metallic silver is partly or wholly replaced by metallic gold. If the silver image is initially converted to silver sulfide, reddish tones are obtained. Pure blue images are obtained by transforming the silver image to a Berlin blue image; the image is first bleached with potassium hexacyanoferrate(III) and then treated with iron(III) chloride for this purpose.

Sodium and potassium selenosulfates convert a silver image directly to a silver selenide image with a brown to purplish-brown tone. In one toning process, the silver image is converted to an organic dye image or such an image is superimposed over it. The steps in this process involve converting the silver image to a silver halide image by reacting it with an oxidizing agent in the presence of chloride or bromide, then converting the halide image to a silver image and to a dye image by reaction with a color developer in the presence of a dye component. The resulting image has a blackish tone. Finally, removing the silver in a bleach – fixing bath leaves behind a pure dye image.

4.3.3.7. Black-and-White Reversal Processing

When a B & W film material is to be processed into transparencies, the film is first developed to a normal negative. The silver metal must then be totally removed without the residual silver halide being disturbed. For this purpose, the negative is treated with a dilute, halide-free solution of dichromate or permanganate and sulfuric acid.

The silver is oxidized and the product silver sulfate goes into solution. The film is then treated with sodium sulfite and exposed in bright light. The silver halide image that results is now developed to give a silver image.

4.3.3.8. Replenishment

Photographic baths in processing machines must be replenished if consistently good results are to be achieved. The developer loses activity for a variety of reasons. Part of the developing agent is oxidized in the development process, a second part by atmospheric oxygen, which is not entirely scavenged by the high concentration of sulfite. Developers containing Phenidone decline in activity as this compound is hydrolyzed. In development, bromide ion from the silver bromide is liberated, builds up in the developer, and restrains development. Protons generated in the development process partly neutralize the alkali, so that, for example, carbonate is transformed into hydrogencarbonate.

A "replenisher" is a solution that restores a conventional bath to its original composition.

Developer Replenisher. A developer replenisher for an exhausted developer should contain high concentration of developing agent and sulfite, pH- correcting agents, and a reduced amount or no bromide. A portion of the exhausted developer is discarded and replaced by the replenisher. In this way, the diminished contents of developing agent and sulfite are restored, while the bromide level in the developer, which has been increased through use, is lowered.

Developing machines operate continuously. Accordingly, replenisher is also added continuously, at a rate in keeping with the amount of photographic material developed. Some overflow usually occurs when the replenisher is added. With some developers, the rate of addition (replenisher rate in mL/m^2) can be matched to the rate of solution removal with the developed material. There is no overflow of developer in these systems. The downstream baths, in contrast, always overflow on replenishment, since the emulsion is already swollen on arrival there and leaves each bath with about the same amount of liquid that it brought in.

Such overflows generally cannot be discharged into sewers. They have to be regarded as liquid waste. It therefore makes sense to regenerate exhausted baths chemically (rejuvenation), so that they can be converted to replenishers and returned to the cycle. Manufacturers of photographic chemicals issue instructions and identify sources for automated preparation equipment (see Section 5.3.1).

Replenishment of Acidic Stop Baths. In order to hold the pH constant in acidic stop baths and prevent too much buildup of developer constituents, these baths are replenished with more strongly acidic solutions.

Fixing Bath Replenishers. Spent fixing baths contain large amounts of dissolved silver, which can be recovered by electrolysis (as metal) or by precipitation (as the sulfide or other sparingly soluble compound). The latter methods are not very important, since the electrolytic method yields high-quality silver in a technically advanced and easily run process. Even so, trimercaptotriazine (trade name TMT) holds some interest as a precipitating agent because its silver salt, in contrast to silver sulfide, is readily filterable [300].

The fixing baths in all developing machines are electrolytically desilvered; in most cases, they are freshened by the addition of a rejuvenator (regenerator), which raises the concentration and corrects the composition. There are two approaches. In the first (off-line desilvering), the overflow from the fixing bath is collected, desilvered, treated with rejuvenator, and returned to the process as replenisher. In the second (on-line desilvering), the fixing bath constantly circulates through the fixing tank and the silver-recovery cell. On the way back to the tank, a rejuvenator concentrate is metered into the desilvered solution to replenish it. This process has the advantage that the silver concentration is held fairly low, so that little silver is carried into the downstream wash-water tanks.

Silver carried in to the wash water in the form of its thiosulfato complexes has a high affinity for the anchor groups of anion-exchange resins. It can thus be significantly concentrated on ion-exchange resins. The wash water, entering with a mean silver content of 30 mg/L, is desilvered to around 1 mg/L. The silver is recovered by re-

generating the ion-exchange resin, then putting the regenerant through electrolysis, or by incinerating the resin [301], [302].

Both replenished and rejuvenated baths quickly come to a relatively steady state with respect to the concentrations of bath constituents, reaction products, and other contaminants. As a result, solutions can be recycled for long periods, often more than a year. They are usually not replaced until the developing machine is serviced.

4.4. Silver Halide Diffusion Processes

The term "silver halide diffusion processes" refers to all black-and-white image-forming processes in which a positive is formed by diffusion reversal [303]. If the silver halide in a donor layer is developed in the presence of a silver complexing agent or fixer, and if this dissolved silver complex is converted to a silver image by physical development on pre-existing metal or metal sulfide centers in an acceptor layer, the negative remains in the donor while a positive with high covering power is produced in the acceptor layer.

A suitable material [304] might take the form of a single-sheet or two-sheet material. The donor layer, like the image receiving (acceptor) layer, can be pulled off (stripping film principle) or transferred to another carrier. Gelatin is not suitable as the colloidal medium for the image receiving layer because of the unsatisfactory covering power of the silver; cellulose derivatives, poly(vinyl alcohol), or colloidal silica are better. It is even possible to make the viscous processing solution serve as the image receiver. Fundamental difficulties (e.g., unacceptable or bronzing image tone and instability of the extremely finely divided positive silver to chemical degradation) have now been remedied. Modern two-sheet systems, such as those for graphics use and for scientific or identification photography, no longer require protective varnishing for the positive.

In the silver halide diffusion process, development generally takes place with a limited amount of developer. This feature has a decisive effect on the photographic result; for example, reproducible development is achieved by the application of a paste film of a well-defined thickness or through the observance of a predetermined immersion time before contact with the receiving sheet. Gradation and sensitivity are also strongly influenced by the availability of silver complex formers (fixing agents). The quantity of fixer can be held surprisingly low, because the fixer is continuously regenerated by the formation of positive silver.

B & W instant-photo materials are manufactured by Polaroid and Fuji; those for technical use, also by Agfa – Gevaert. Polaroid further markets B & W instant transparency films for graphic-arts use and for continuous tone reproduction. The Polachrome instant transparency film is a black-and-white material with an additive linear screen. See, → Imaging Technology, Chap. 2.2.3.1. .

5. Color Photography

The purpose of color photography is to reproduce in pictures all the color impressions received by a normally sighted person. Color photography takes advantage of the fact that all perceived colors can be generated by the juxtaposition or combination of just three primary colors in various proportions.

There are two sets of primary colors: additive primaries (blue, green, and red; see Section 5.1) and subtractive primaries (cyan, magenta, and yellow; see Section 5.2).

5.1. Additive Color Processes

Each of the colors blue, green, and red transmits a third of visible light (a third of the solar spectrum) and blocks the other two-thirds. The same holds for light reflected from these colors. Accordingly, color images can be created with blue, green, and red light rays. Three projectors (blue, red, and green) are needed; their light is modulated by three distinct black-and-white transparencies and projected onto a white screen in a dark room (Fig. 39).

To create a color image, suitable B & W emulsions and color filters (blue, green, and red) must be used to make three separate images, which are processed into B & W transparencies. The transparencies are placed in three projectors together with the respective color filters, and the three images are projected one over another. Prints (for

viewing by reflected light) cannot be made by the additive process.

Figure 39. Principle of additive color mixing
Beams of the three primary colors (blue, green, and red) are projected onto a white wall (shown here as black) in a dark room. The addition of two primary colors gives the mixed colors cyan (blue and green), magenta (blue and red), and yellow (green and red). All three primaries together give white.

5.1.1. Screen Color Plates and Films

In order to decrease the amount of equipment required, the LUMIÈRE brothers marketed the first screen color plates in 1907. These "Autochrome" plates contained color filters in the form of individual starch grains, dyed blue, green, and red, in a layer just one grain thick on top of the panchromatically sensitized emulsion. The emulsion was exposed through the screen of dyed grains. After reversal processing, the color transparency could be viewed only by transmitted light. A single image, with gray-tinted colors, resulted.

The color screen had to be so fine that the color elements could not be separated by the eye. Only in this way was it possible to perceive yellow as a consequence of red and green dye particles lying next to each other.

In 1977, Polaroid put a narrow-gauge instant film with a linear color screen (Polavision) on the market, following it in 1982 with an instant transparency material (Polachrome); see Sections 5.5.4.1 and 5.5.4.2.

5.1.2. Lenticular-Screen Film (Agfa, 1932)

The lenticular-screen film bore a very fine screen of cylindrical lenticules on its back. The film was exposed through this screen with the aid of a special filter, which had the colors blue, green, and red next to one another. After reversal processing, the film had to be projected with the same filter.

5.2. Subtractive Color Processes

5.2.1. Principle

The subtractive primary colors cyan, magenta, and yellow each transmit two-thirds of the spectral colors and absorb only one-third. Cyan dye, for example, absorbs red light and passes blue and green without hindrance (B in Fig. 40). The same holds for reflected light. Accordingly, cyan is sometimes called "minus-red"; magenta, which absorbs only green, as minus-green (Fig. 40 C); and yellow, accordingly, as minus-blue (Fig. 40 D).

With the three subtractive primaries, all perceptible colors can be reproduced in either transmitted or reflected light. If magenta is superimposed on cyan, the magenta absorbs green light not absorbed by the cyan, and a pure blue is obtained in transmitted or reflected light (E in Fig. 40). If magenta and yellow are combined, pure red remains (F in Fig. 40). Yellow and cyan give pure green (G in Fig. 40). All modern color processes are based on these three subtractive primaries.

In subtractive color processes, white is therefore represented by a transparent film (Fig. 40 A), so that all the light from the projection lamp is passed. In other words, no color is subtracted from the white light. This is one of the main advantages of subtractive processes. In contrast, white in the additive process is obtained by the addition of all three primaries, but each of these contain only a third of the white light intensity from the projection lamp.

Subtractive color processes require three colored images: yellow, magenta, and cyan. They are not, however, prepared with the help of filters and an emulsion sensitive to all colors, as in the additive process. Instead, three emulsions are

used, each sensitive to only one of the three primary colors. In most subtractive processes, the sensitive emulsions are coated one over another on a support. In this way, the three layers can be exposed simultaneously in a single camera.

There are three major groups of subtractive color processes, all of which presuppose the development of a silver image:

1) *Chromogenic (dye-coupling) processes*, in which the dyes are developed. These are further subdivided into *negative–positive* and *reversal processes*.
2) *Silver dye bleach (chromolytic) processes*, in which dyes present at the outset are bleached in such a way as to form an image.
3) *Dye-transfer processes* (Technicolor, Dye Transfer, instant photography systems).

For explanation of A, B, C, D, E, F, G, H see text.

5.2.2. Processes with Chromogenic Development

The greatest advance in color photography was the discovery of chromogenic development. Chromogenic methods have become the most important ones in color photography. The color developer that is oxidized in developing the silver image usually reacts with colorless reactive substances (dye components, dye couplers) to form a variety of dyes. The principle of this method was described in 1911 by R. Fischer and H. Sigrist [305]. It can be schematically represented in the following way:

Exposed silver halide + color developer → silver metal + oxidized developer

Oxidized developer + dye coupler → dye

Two types of materials employ this process. *Reversal films* of the Kodachrome type have no couplers in the emulsion layers (see Section 5.2.2.5). Instead, the dye couplers are dissolved in various color developer baths. When these materials are processed, each dye coupler must diffuse, along with the color developer, into the emulsion layer for which it is intended. The development process is very complicated and hence can be carried out only with special machinery in special laboratories. It has the advantage of high sharpness because the emulsion layers in the material are very thin.

In materials of the *Agfacolor type* (Kodacolor, Fujicolor, etc.), the dye couplers are embedded in the three emulsion layers, from which they cannot escape by diffusion (see Section 5.2.2.2). Because these materials are developed in a single developer solution, the process is much simpler and can even be performed by amateurs.

5.2.2.1. Color Developers

Until recently, the only substances that could satisfy the many requirements that a color developing agent must meet were *N,N*-dialkylated *p*-phenylenediamine derivatives (**48**) [306]. Table 2 lists the most important developing agents now in use.

48

Of the agents in Table 2, only two are in common use: CD-3(**48d**) for color negative papers, reversal color films, and reversal color papers; CD-4 (**48e**) for color negative films. These substances, in alkaline solution, can reduce exposed silver halide. Initially, a semiquinonediimine is formed. After further oxidation, a quinonedi-

Table 2. The most important color developers

Compound	R^1	R^2	R^3	Trade name
48a	H	C_2H_5	C_2H_5	TSS
48b	H	C_2H_5	C_2H_4OH	T 32
48c	CH_3	C_2H_5	C_2H_5	CD-2
48d	CH_3	C_2H_5	$C_2H_4-NH-SO_2CH_3$	CD-3
48e	CH_3	C_2H_5	C_2H_4OH	CD-4
48f	CH_3	C_2H_5	$C_2H_4OCH_3$	CD-6
48g	H	C_4H_9	$C_4H_8-SO_3H$	T 60

imine cation is produced from this intermediate (**49** is the benzoid resonance structure with the electron sextet on the nitrogen). This quinonediimine reacts with the carbon atom of the active methylene group of the dye coupler to form a leuco dye (**50**).

The leuco dye is dehydrogenated to the dye (**51**) by a second developer molecule (also oxidized by silver halide) by atmospheric oxygen, or iron(III) compounds. To form one molecule of dye requires a total of four oxidation equivalents (electrons) (see nxt page, top).

If the coupler molecule has an easily removable leaving group (e.g., halogen, mercapto, sulfo, azo) at the point of attachment instead of a hydrogen atom, this group can be split off together with the hydrogen on the nitrogen. In this case, only two oxidation equivalents are required ("2-equivalent couplers").

Color Intensification. Processes have been devised in which the maximum quantity of dye formed depends not on the stoichiometric quantity of image silver formed, but only on the quantity of dye coupler that is present. Only a catalytic amount of image silver is needed for dye formation.

If a silver-poor color material, containing the normal quantity of dye coupler but only part of the normal amount of silver halide, is developed normally, the color in the resulting image is of low density. If the material after development, still saturated with developer, is placed in an oxidizing bath, for example with hydrogen peroxide [307] or hexaminecobalt(III) chloride [308], then the color developer will be oxidized by the oxidant at the locations where silver metal has been formed. Silver metal has a catalytic action. As a result, additional image dye is formed. The cobalt(III) complex can even be added to the developer itself, since this complex does not attack the developing agent in the absence of metallic catalysts, and color intensification begins after normal development of the exposed silver halide. The color intensification process has not gained much importance, but in the future it may become important depending on the silver economy.

5.2.2.2. Dye-Forming Couplers

p-Phenylenediamines can form various oxidation products in the photographic development of a latent image; for example in the following reaction:

It gives up two electrons as well as one proton. The products are two silver atoms, one developer oxidation product (DOP), and one proton. If this DOP can now be utilized to produce a variety of dyes, it can form the basis of a color process. R. Fischer [305], [309] stated that oxidized *p*-phenylenediamines can be coupled with special organic compounds to form dyes. These compounds have long been referred to as dye-forming couplers.

$$\text{DOP} + \text{Dye-forming coupler} \xrightarrow[-H_2O]{OH^-} \text{Dye}$$

The requirement for obtaining a multicolored image is that the same DOP, combined with three distinct dye-forming couplers, gives yellow, magenta, and cyan coupling products:

Dye-forming coupler 1 + DOP ⟶ Yellow dye
Dye-forming coupler 2 + DOP ⟶ Magenta dye

Dye-forming coupler 3 + DOP ⟶ Cyan dye

Dye-forming couplers themselves are usually colorless, whereas the dyes derived from them have the highest possible extinction in the desired portion of the spectrum.

A desirable feature in dyes is a narrow absorption curve (small half-width) with only small side absorptions in adjacent parts of the spectrum.

Dyes and dye-forming couplers for photographic materials must have a number of other qualities in addition to an absorption in the desired spectral range, e.g.:

- Color purity
- High coupling activity
- High extinction
- High sensitivity
- Low fog
- Good solubility
- Good emulsion stability
- High dark stability
- High stability under tropical climatic conditions
- Good light stability
- Low granularity
- Availability (low price)

All these special requirements can be controlled within certain limits through appropriate substitution in the dye-forming coupler molecule. In many cases, however, a compromise is necessary when the requirements are in conflict (e.g., high coupling activity versus low fog).

Yellow Couplers. Dye-forming couplers that form yellow azomethine dyes are called "yellow couplers." They have an absorption maximum (λ_{max}) in the blue region, preferably between 430 and 460 nm.

The methylene group at the coupling position is activated by two adjacent carbonyl groups; the simplest yellow couplers are β-diketones or acylacetamides.

By far the most widely used yellow couplers are benzoylacetanilides and pivaloylacetanilides (2,2-dimethylpropanoyl acetanilides). The following list gives a rough comparison of these two classes of couplers.

Coupling activity	higher	lower
Sensitivity	higher	lower
Fog	higher	lower
Color reproduction	longer wavelengths (redder)	shorter wavelengths (yellower)
Light stability	lower	higher
Dark fading stability	lower	higher
Stability under tropical conditions	lower	higher

Because of their better dye stability [310], pivaloylacetanilide yellow couplers are used in all color papers. The other properties can be modified within certain limits by appropriate substituents (R^1, R^2, R^3, R^4) in the benzoyl and aniline parts. In order to anchor the coupler in one particular layer of a photographic material, at least one of the substituents (R^1, R^2, R^3, R^4) must be a "ballast" group: i.e., an organic substituent that is large enough to prevent diffusion into an adjacent layer. The following substituents can be used:

R^1: 2–OCH_3, 2–$OC_{16}H_{33}$, 3–NH–CO–$C_{15}H_{31}$
R^2: 4–OCH_3, 4–$OC_{16}H_{33}$,
R^3: 2′–Cl, 2′–OCH_3, 2′–$OC_{16}H_{33}$

R^4: 5′–$COOC_{14}H_{29}$, 5′–NH–CO–$(CH_2)_3$–O–

5′–OCH_3, 5′–SO_2–NH–CH_3, 5′–SO_2–N(CH_3)(CH_3)

5′–NH–SO_2–$C_{16}H_{33}$, 4′–SO_2–N(CH_3)(CH_3)

Extensive research has shown that the Hammett equation adequately describes the effects of various substituents and their position on pK_a [311], λ_{max} [312], coupling kinetics [313], and hydrolytic stability of dyes [314], [315].

Magenta Couplers. By analogy with yellow couplers, compounds that form magenta dyes on oxidative coupling are called magenta couplers. In contrast to open- chain methylene compounds, the oxidative coupling of cyclic compounds with an active methylene group leads to dyes having absorption maxima in the range of 530 – 580 nm. The major types of compounds can be summarized as follows (see page 78, top).

The absorption maximum shows a bathochromic shift of ca. 100 nm in comparison to that of yellow couplers and is preferably between 540 and 560 nm in the green part of the spectrum. Of the many known coupler structures, only a few have actually found use in photographic materials. Examples include the pyrazolones (**57**), the pyrazolobenzimidazoles (**58**) and (in 1983 – 1984) the two isomeric pyrazolotriazole structures (**59**, **60**).

Pyrazolone Magenta Couplers. For many years, all the magenta couplers used in photographic materials had a pyrazolone structure with a phenyl nucleus in the 1 position. The substituent in the 3 position of the pyrazolone ring, a phenylamino group or an acylamino residue, largely governs the properties as well as the potential applications. A comparison of the effect of these two substituents is given in the following list:

Coupling activity	higher	lower
Sensitivity	higher	lower
Light stability	higher	lower
Dark stability	higher	lower
Stability under tropical conditions	higher	lower
Granularity	higher	lower
Absorption	shorter	longer

Accordingly, anilinopyrazolones were preferred for color papers because of better dye stability, while acylaminopyrazolones were used in film materials (color negative and color reversal) because of their lower granularity. In both classes, the 1-phenyl nucleus has three chlorine substituents in the 2,4,6 positions. The reasons for this is that the residual coupler [310] in the emulsion showed less yellowing and the dye stability is markedly improved.

The light stability of anilinopyrazolones can be further improved by the use of special stabilizing residues in the ballast part of the molecule, for example:

Pyrazolobenzimidazoles. The cyclization of 1-(2-aminophenyl) pyrazolones to pyrazolobenzimidazoles by elimination of water is easily carried out:

These compounds couple with developer oxidation products (DOP) of the phenylenediamine type to give magenta dyes of great brilliance. In contrast to the conventional pyrazolone magenta dyes, these do not have a secondary absorption maximum in the blue region. The usual substituents R^1 are alkyl, acylamino, arylamino, and alkoxy groups.

Pyrazolotriazole Magenta Couplers. Closely related to the pyrazolobenzimidazoles are magenta couplers of the pyrazolotriazole type. These again show high color brilliance, having no secondary absorption in the blue part of the spectrum. Of the two structural isomers available, the pyrazolo[3,.2,- c]-5-triazoles

have been known since the mid 1970s [316], [317], but they were not used in photographic materials until 1982. Dyes from 1 *H*-pyrazolo[1,5-b] [1,2,4]triazole magenta couplers

were described as magenta couplers in 1983 – 1984; they are used in modern color papers because of their good light stability [318].

Cyan Couplers. Compounds whose azomethine dyes absorb in the red region of the spectrum are called cyan couplers. In all, five distinct types of structure in the class of phenols and naphthols are common:

Dyes formed from CD-3 (see Table 2) and couplers **61** and **62** absorb at ca. 660 nm and are used in color papers (**61**) and color reversal film (**62**). The dyes from **61** offer especially good dark and light stability.

When color negative films are processed with developers containing CD-4, couplers **63–65** give dyes that have an absorption maximum at 690 – 700 nm. Important features are the good sensitivity of naphtholic coupler **65** and the good dark fading stability and good re-oxidizability of the leuco dyes from couplers **63** and **65**.

5.2.2.3. Special Dye Couplers

If a coupler has a suitable substituent X at the coupling position, the reaction with DOP does not give the leuco dye but goes directly to the azomethine compound (see Section 5.2.2.1).

As only two equivalents of Ag^+ are needed per mole of dye formed, couplers with these leaving groups X≠H are called 2-equivalent couplers.

Normal 2-Equivalent Couplers. Substituents X with no special sensitomeric action include

Compounds bearing these substituents have the advantage of a low silver consumption.

Development Inhibitor Releasing Couplers. Another group of special 2-equivalent couplers are development inhibitor releasing (DIR) couplers. Certain leaving groups X called inhibitors, such as

diffuse to the silver halide crystal after being split off. Because of its strong affinity to silver halide and silver metal, the inhibitor is adsorbed on the surface of the grain. In this way, the further reduction of silver halide to metallic silver is inhibited.

Inhibitors can develop their action in the layer where they are liberated or can diffuse into neighboring layers. Intralayer and interlayer effects are therefore distinguished.

Intralayer effects
Control of granularity
Control of sharpness through edge effects

Interlayer effects
Improvement of color reproduction through interimage effects

DIR couplers are assigned to one of two groups depending on whether the inhibitor is released immediately on coupling or by an additional chemical reaction (e.g., cyclization or elimination). An example of a DIR coupler of the second type is

Development-Accelerator-Releasing Couplers [319]. In contrast to DIR couplers, development-accelerator-releasing (DAR) couplers split off a development accelerator or a fogging agent. An example of a DAR coupler is the following:

The formylphenylhydrazine group, once liberated, is oxidized to the acylphenyldiazene; the latter then forms a phenyldiazene that can serve as a nucleating agent for unexposed silver halide [320].

Non-Color-Forming Couplers. Couplers that bear an alkyl group (e.g., methyl or ethyl) at the coupling position can still form a coupling product in the usual way with DOP. However, subsequent base-catalyzed elimination of the alkyl group as an alkyl anion is not possible, and no dye formation takes place. For this reason, compounds of this type are called non-color-forming couplers (white couplers). They are included in interlayers as DOP traps in order to prevent its diffusion into the adjacent layer.

Masking Couplers [321], [322], [323]. Couplers with a dye attached via the leaving group (**66**) or that have an intrinsic color by virtue of the leaving group (**67**) are called masking couplers (see next page, top).

They are employed to correct undesired side absorptions of the image dyes. The action of the yellow masking coupler **67** is given as an example. In development, it recouples with DOP; the yellow density of **67** decreases and a magenta dye is formed upon coupling with DOP (Fig. 41). The sum of curves b and c gives the relatively constant density d, which practically corresponds to a magenta dye with no blue absorption. The uniform yellow fog can be filtered out with a blue filter in printing.

A similar discussion applies to the red masking coupler **66**, which couples to cyan and is used to compensate the side absorption of cyan dyes in the green region of the spectrum. The masking dye, which is present as a leaving group, has a high water solubility by virtue of its two sulfo groups and is washed out in processing.

Bleach Accelerator Releasing Couplers. Couplers having a bleach accelerator, for example –S–CH_2–CH_2–COOH, as leaving group are called bleach-accelerator-releasing (BAR) couplers [324].

The group liberated upon coupling effects the desilvering of the photographic material in rapid processing when the bleaching time is short or when exhausted bleaching baths are employed.

Figure 41. Action of a yellow masking coupler generating a magenta dye
a) Gradation of a magenta dye; b) Yellow gradation due to secondary density of magenta dye; c) Decrease in yellow density due to recoupling of **67**; d) Compensated yellow density (resultant of b and c)

5.2.2.4. Anchoring of Dye Couplers in Layers

The dyes must be generated in three superimposed emulsion layers without interfering with color reproduction. The layers must therefore be extremely thin; however, the coupler must not be allowed to diffuse from its own layer into an adjacent one (interlayer wandering).

This diffusion resistance, which is necessary for good color separation, can be attained in a variety of ways.

Aliphatic "Tail". If a long-chain hydrocarbon residue containing hydrophilic sulfonic acid

or carboxyl groups is attached to the dye-coupler molecule, it will prevent the coupler from escaping its layer. The hydrophilic groups facilitate the introduction of the coupler into the emulsion layer as a salt. The low diffusivity results not only from the size of the molecule and the "tail" (large hydrophobic group); these couplers also interact with the gelatin binder, forming micelles, which hinder diffusion. Examples of micelle-forming couplers are:

Solvent Dispersion Couplers. In 1942, Kodak introduced a film employing a different method for anchoring the couplers against diffusion. The hydrophobic couplers are dissolved in a highboiling organic solvent (e.g., tricresyl phosphate or dibutyl phthalate), dispersed in gelatin with suitable aids (e.g., Alkanol XC), and added to the silver halide emulsions. The resulting emulsion layers contain the couplers in the form of very finely divided oil droplets, into which the oxidized color developer penetrates and where the dye-forming reaction takes place. The chemical structure of the groups hindering diffusion is different from that of micelle-forming couplers, in keeping with the technical requirements: The straight- chain hydrocarbon group is replaced with a highly branched and bulky group such as

which is joined to the coupler molecule by a group. The high-boiling solvents used as the oil phase further protect the coupler and the dye from the action of moisture, heat, and light.

Coupler-Loaded Latex. The direct mechanical dispersion of hydrophobic couplers in the emulsion layer requires a relatively large amount of energy and often yields dispersions with a broad disperse-phase size distribution. These disadvantages can be avoided if a polymer dispersion is used and the hydrophobic coupler is deposited on the surface of the latex particles from a solvent miscible with water. In this way it is possible to obtain coupler dispersions with a very narrow particle-size distribution and good photographic qualities. On account of their affinity for the hydrophobic latex particles, the coupler molecules deposited in this way are fixed to the surface of the latex particles and are virtually prevented from diffusion.

Polymeric Couplers. Low-molecular-mass coupler molecules without a ballast group but having a polymerizable group can be anchored in a different way. They can be polymerized with suitable comonomers and small quantities of cross-linking monomers (e.g., divinylbenzene, ethylene glycol diacrylate, trimethylol propene triacrylate) into "latex couplers." The latex particles, which embody the coupling action, are much smaller than those of dispersed couplers and have no tendency to increase in size.

Some appropriate coupler monomers are as follows:

Examples of compounds used as comonomers are acrylates, acrylamides, and styrenes. The coupling activity, the granularity, the stability of the emulsion layer, and the stability of the dyes can be controlled within certain limits by the choice of comonomer.

Because the coupler monomer and the comonomer (ballast portion) are in a favorable ratio and no oil-phase former is needed, latex couplers make it possible to obtain much thinner emulsion layers than dispersed couplers.

5.2.2.5. Couplers Added to Developer

As an alternative to incorporating the couplers in the materials, Kodak devised another process for making positive color transparencies. The dyes are produced from conventional developers and the known couplers. In this process, however, the couplers are not fixed in the several emulsion layers but are added to the developing solutions. The dye-forming couplers are readily soluble in the alkaline baths, but upon chromogenic development they produce dyes that are sparingly soluble; hence, they cannot be washed out in subsequent processing. Suitable choices are low-molecular-mass compounds with enolizable carbonyl groups or phenolic OH groups, such as:

After exposure of the color transparency film, a black-and-white negative is developed. The dyes are then produced one after another, not simultaneously, and the positive color image is obtained by a combination of reexposures behind narrow-band filters:

1) The cyan image is formed in the red-sensitive emulsion by exposure through a red filter and development in the presence of the cyan coupler.
2) The yellow image is formed in the blue-sensitive layer by exposure through a blue filter and development in the presence of the yellow coupler.
3) The magenta image is formed by chemical fogging; that is, the silver nuclei are generated not by exposure but by treatment with sodium borohydride. Development in the presence of a magenta coupler follows.

This complicated process requires exact control of the conditions and can be performed only with special equipment. In spite of this difficulty, the process, which gives particularly sharp images, has remained important.

5.2.2.6. Chromogenic Negative – Positive Processes

In color negative film, a silver image and a dye image are obtained after exposure and development. Because each dye has the color complementary to the sensitivity of the emulsion where it is produced, bleaching and fixing of the silver image yields a color image that is complementary with respect to lightness and color (a negative). What was blue in the original is yellow in the negative; red appears as cyan; and green appears as magenta. What was black in the original

shows up as white or transparent in the negative, while what was white appears black.

Color Recording Material. The requirements imposed on color recording materials today are very stringent; they cover light sensitivity, reproduction of details and colors, and other qualities. As a result, these materials have a much more complex structure than color print materials. As an example of a modern, high-speed recording material, the structure of Agfacolor XRG-100 negative film will be discussed (see Fig. 42) [325]. The color-forming layers in this film are applied as double coatings. Double-coating involves combining a relatively coarse-grained, high-speed emulsion having a low ratio of couplers to silver with a relatively low-speed, fine-grained emulsion having a higher ratio [326]. The resulting film offers high light sensitivity with very fine color grain. Since each emulsion acts as a gray filter, diminishing the exposure of the emulsion beneath it, the high-speed coating is always applied on top of the lower-speed one. The uppermost emulsions are the two blue-sensitive yellow layers. Immediately below them is a yellow filter layer consisting of colloidal silver. This layer prevents the green-sensitive and red-sensitive emulsions from being exposed in the blue intrinsic sensitivity region of the silver halide. The green-sensitive magenta emulsions are separated from the red-sensitive cyan emulsions by a filter layer containing a red dye. This enhances the sharpness by reducing the back-scattering of green light and also contributes to improved color separation. Beneath the red-sensitive cyan emulsions is the black antihalation layer. This protective layer, consisting of colloidal silver, prevents the transmitted light from being reflected at the emulsion support. The colloidal silver in the yellow filter layer and the antihalation layer are oxidized in the bleaching bath and dissolved out in the fixing bath. The green-sensitive emulsions contain yellow masking couplers, whereas the red-sensitive emulsions contain red masking couplers. These masking couplers (see Section 5.2.2.3) are colored substances, which change their color in development in relation to the density of the negative and so compensate for undesired secondary absorptions of the image dyes. Masking makes the colors purer and more brilliant. DIR couplers (see Section 5.2.2.3) are also present in all the light-sensitive layers. This decreases the granularity (see Section 6.2.2) and improves the sharpness (see Section 6.2.3) and the color reproduction by virtue of edge and interimage effects (see Section 6.1.6), respectively.

Figure 42. Schematic coating structure of a high-speed color negative film

The emulsion support of 135 size film consists of cellulose acetate 125 µm thick. The emulsion thickness is 23 µm. The film is processed by the Agfacolor AP-70, AP-71, or AP-72 process or the Kodak C-41, C-41 B, C-41 BNP, C-41 RA, or C-41 RANP process.

Positive Print. To obtain a color positive, the color negative must be printed onto a color positive material (emulsion side to emulsion side). After processing, the result is a positive corresponding to the original with respect to color and lightness gradation. A flow sheet of the entire chromogenic negative – positive process is shown in Figure 43. Since the positive material has a very high gradation and its blue-sensitive layer is markedly faster than its green-sensitive and red-sensitive emulsions, the yellow filter layer can be dispensed with. The arrangement of color emulsions can also be different. In color paper, in contrast to the recording material, the topmost light-sensitive layer forms the cyan par-

tial image and the layer forming the yellow partial image is the undermost one.

The printing process allows the use of color correcting filters. If one color is reproduced too strongly in the positive relative to the other two in the positive, a correcting filter can be inserted in order to restore the color balance.

Color positive papers have "selective" sensitization, unlike the "overlapping" sensitization of negative films; that is, the spectral sensitivity curves of the three emulsions in papers have little or no overlap. The sensitization maxima must be in close agreement with the extinction maxima of the color negative dyes corresponding to the respective positive emulsions.

5.2.2.7. Reversal Color Process

The reversal color process leads, in a single step, to a positive in which the lightness and color of the developed photographic material correspond to those of the original object. If a transparent support is used, a transparency is obtained: a positive intended for viewing in transmitted light (projector or viewer). To obtain a positive in one operation, the photographic material passes through two development steps in the reversal color process. In the first development, a black-and-white negative is obtained. The undeveloped silver halide is subsequently either exposed or chemically fogged, then put through a second, chromogenic development, which "reverses" it to give a positive silver and dye image. The silver formed in both the first and second developments is oxidized in the same bleaching bath and converted to silver bromide, which is complexed and dissolved in a downstream fixing bath and then washed out of the emulsion. Figure 44 is a schematic diagram of the reversal color process.

Reversal Color Recording Materials. Two types of reversal color films are on the market. They differ in layer structure and in processing. Films of the *Kodachrome type* contain no dye couplers; the couplers are introduced only during development, and three color developments are required in addition to the first development (see Section 5.2.2.5). In film materials of the *Agfachrome type* (Ektachrome, Fujichrome), the couplers are incorporated into the emulsions and cannot diffuse away from their location. The structure of such a film is explained for the example of Agfachrome CT-100 (see Fig. 45).

Figure 45. Structure of a color reversal film with incorporated couplers

In *Agfachrome CT-100*, the color-forming layers are double-coated; that is, the light-sensitive emulsions and the couplers for the three

subtractive primary colors yellow, magenta, and cyan are each applied in two coatings. For the same reasons as in the case of color negative film, the upper coating of each color element has a higher speed than the lower one. In contrast to color negative materials, the higher-speed emulsions in reversal color materials have a higher relative content of couplers than the lower-speed emulsions. This arrangement offers low granularity despite the high sensitivity. In addition to the color-forming emulsion layers, Agfachrome CT-100 further includes a number of separating and filter layers. The UV filter layer absorbs the ultraviolet portion of the light incident on the film during exposure, thus preventing color distortion due to UV radiation. Yellow and red filter layers and the antihalation layer have the same functions as in color negative films (see Section 5.2.2.6). The separating layers contain substances which prevent developer oxidation product from diffusing into adjacent emulsion layers and causing color distortion. Sometimes they also contain substances that control interimage effects. The colored masking couplers included in color negative films to improve color reproduction (see Section 5.2.2.3) cannot be employed in reversal color films, because the intrinsic colors of such couplers distort the color reproduction.

Development inhibitor releasing (DIR) couplers, which are very useful in color negative films, cannot exert their full effect in the reversal process. The reason lies in the very intensive chromogenic second development, in which complete development of the silver halide is sought and even inhibited silver halide cannot survive. Even so, under certain conditions DIR couplers can be advantageous in improving image quality in reversal color films. For example, Gevachrome II films, which are intended chiefly for television purposes, contain such couplers.

Films of the Agfachrome type today are virtually all compatible with the E-6 process; that is, they can be processed by the Kodak E-6 process or in similar processes marketed by various manufacturers (see Section 5.2.2.4).

Reversal Color Printing Materials. Film prints can be made from positive transparencies on reversal color copy films. These films have the same basic structure as recording films and are processed in the same way, but they have a lower contrast than recording films. Paper prints from positive transparencies can be made by way of an internegative. This process requires two operations, the preparation of a negative from the transparency on negative film and the printing of this negative on color negative paper. A better and faster method is to print the positive transparency on reversal color paper. In this way, a positive print is obtained in one operation (see Section 8.3.1.2).

5.3. Processing of Color Photographic Materials

The most important processing steps for color photographic materials are as follows.

Development. In this step, a silver image and a dye image are formed in each of the emulsion layers (see Section 5.2.2.1). Along with the silver and dye images produced in exposed regions, fog is also formed in unexposed regions under certain conditions. There can be several causes of fogging [327]. *Base fog* is the coloration of the support and emulsion layers due to sensitizers etc. *Development fog* is generated in the developer. *Postdevelopment fog* forms by reduction of unexposed silver halide grains in subsequent washing, if there is such an operation. *Bleaching fog* can arise in the emulsion layers as a result of residual color developing agent, which is oxidized in the bleaching bath or bleach – fixing bath and then couples with unconsumed coupler to form a dye. Bleaching fog can be largely suppressed by adequate washing or stopping before the oxidizing bath or by the maintenance of the lowest possible pH in the bath itself. "White couplers" (non- color-forming coupler) are effective in suppressing bleaching fog (see bleach – fixing below).

Silver Bleaching. Because the blackening inherent in the silver image distorts the color image, this silver must be bleached (oxidized) without disturbing the image dyes. This step involves oxidizing agents, such as the iron (III) – EDTA complex, hexacyanoferrate(III), or potassium peroxodisulfate ("persulfate"). Depending on the composition of the bleaching bath, a silver salt (halide, hexacyanoferrate, or sulfate) or a complex salt of silver is formed. In addition to

the developed silver, the metallic silver in the yellow filter layer and antihalation layer are also oxidized in the bleaching bath.

Fixation. Both the undeveloped silver halide and the silver salt formed in silver bleaching must be removed from the color material so that these light-sensitive silver salts do not affect the process at a later stage. Sodium or ammonium thiosulfate is used almost without exception for fixing. Ammonium thiocyanate is sometimes added to speed up fixation.

Bleach – Fixing. To save a step, it is possible to use a bath that carries out the functions of bleaching and fixing. Bleach – fixing baths contain the iron(III) complex of an aminopolycarboxylic acid (most commonly EDTA) as oxidizing agent for silver metal, along with a thiosulfate as complexing agent for oxidized silver. In addition, these solutions contain free complexing agents to stabilize the iron complex and sulfite to stabilize the thiosulfate. Bleach accelerators, such as mercapto compounds of triazole and thiadiazole, may also be present. White couplers, i.e., suitably substituted pyrazolones (see Section 5.2.2.3) are also incorporated into these solutions. White couplers react with developer oxidation products (carried into or generated in the bleach – fixing bath) to form colorless products, before these oxidation products can combine with the couplers in the emulsions to form nonimage dyes (bleaching fog).

Stabilization. The concept of a developing machine without a water supply or a water drain led to the use of stabilizing baths (not to be confused with those described in Section 4.3.3.4). These baths make the use of wash water superfluous. The iron complex originating from the bleach – fixing bath that remains in the emulsions must be prevented from altering the highlights and colors of the image after long storage. The principal ingredient of such a bath is a phosphonic acid, such as hydroxyethanediphosphonic acid (HEDP), which "masks" the iron ion; i.e., accepts it from the EDTA complex. The ferric complex of HEDP is not able to take part in redox reactions [328]. This step occurs in film and paper processing. A film processor and a paper processor with an exposure unit at the head end constitutes a "minilab" (see Section 5.6.3).

Because the color materials marketed by various manufacturers have similar physical and chemical properties, there is little difference between processing techniques. This principle of compatibility dominates the market. In the extreme case, it means that color films and color papers from all the major manufacturers can be processed alongside one another even if each bath comes from a different chemical manufacturer. Exceptions to this rule are few and apply only to special-purpose products.

The equipment used for processing influences the operating conditions: development can take place in a tray, a drum, or a roller transport or leader-belt machine. Machines with low throughput and long idle times at high temperature may require more than the usual amount of antioxidants (e.g., for the developer).

5.3.1. Replenishment and Rejuvenation

The baths used for the processing of color materials are chemically modified during processing. For example, halides, stabilizers, protective dyes, wetting agents, gelatin particles, and other soluble constituents of the emulsion layers build up in the *developer*. The *bleaching* and *bleach – fixing baths* become enriched in developer ingredients, and silver collects in the bleach – fixing and fixing *baths*. In principle, the same discussion applies to the replenishment and rejuvenation (regeneration) of color photographic baths as to those of B & W baths (see Section 4.3.3.8). The processing of color materials is almost completely automated, regardless of the size of the laboratory. The baths are continuously replenished and replaced. All the manufacturers of photochemicals strive to offer *replenishers* that can be added in the smallest possible amounts, so as to minimize the quantity of waste and thus the cost of shipping it.

A further reduction in processing waste is achieved by *rejuvenation* (regeneration). In larger operations especially, overflows from all the major baths are reprocessed and recycled (rejuvenated or regenerated). Color developers are rejuvenated on anion-exchange resins, which selectively adsorb the halide. The solution, now with little or no halide, is then topped up with

the rejuvenator, which replaces the substances consumed and makes up the volume of solution lost through entrainment. In this way a ready-to-use developer replenisher is obtained. When the ion-exchange resin is exhausted, it must be regenerated, usually with sodium chloride and/or sodium hydrogencarbonate solution. The entire rejuvenation process is carried out in mainly automated equipment [329].

Most *bleaching-bath rejuvenation processes* are simple. The principal bleaching agents used – iron complexes of aminopolycarboxylic acids – oxidize even on standing in the presence of air, so that the concentrated rejuvenator solution can be added without further treatment. The volume of developer solution or water brought into the bath with the materials is turned into bleaching solution by the rejuvenator. Bleaching baths with hexacyanoferrates are now seldom used, they require a peroxodisulfate for the reoxidation of the bleaching agent. The result is a buildup of sulfate, which can become a bleaching inhibitor after a long period of closed- cycle operation.

Rejuvenation of bleach – fixing baths involves one special difficulty: the iron(III) complex that has not been reduced during silver bleaching must be reduced before reduction of silver can occur. The steel-wool process originally used for silver recovery involved the deposition of silver on finely divided iron (cementation), but the reaction of the iron(III) compound with the metallic iron, which takes place first, led to an undesirable silver sludge product. The first satisfactory outcome was achieved with a modified process in which the iron(III) compound was reduced with sodium dithionite before the inlet to the steel-wool cartridge [330]. Since equipment providing a high electrolysis current has become available, however, the most widely used process is electrolytic silver deposition. Once the silver has been recovered, the iron complex, which has been completely reduced in the process, is oxidized with air. The rejuvenator then brings the solution to the desired replenisher concentration.

For the rejuvenation of fixing baths, see Section 4.3.3.8.

5.3.2. Processes and Formulas for Color Photographic Materials

The formulas set forth by the various manufacturers of photographic chemicals are essentially similar, because the world market honors the principle of compatibility; that is, materials sold by all manufacturers can be processed in a satisfactory way regardless of the supplier of the chemicals used. There are, however, marked differences between brands of chemicals as to handling, stability, and environmental impact.

To simplify the preparation of baths from prepackaged processing chemicals, what is supplied is usually just the replensiher chemicals. A ready-to-use tank charge is obtained by adding "starter" solutions to the replenisher solutions. The starter solutions act mainly to set the proper halide concentration and pH.

5.3.2.1. Processing of Color Negative Film

An example of a process for color negative film is the Kodak C-41 process. Variants are C-41 B and C-41 RA, intended chiefly for minilabs. Agfa markets a corresponding process as AP-70, with variants AP-71 and AP-72 for minilabs. The processing conditions of these processes are shown in Table 3 [331].

Table 3. Sequence of baths in the processing of color negative films

Bath	Processing time, s	Temperature, °C
Process C-41/AP 70		
Developer	195	37.8 ± 0.25
Bleaching	260	38 ± 3
Intermediate washing	65	38 ± 3
Fixing	260	38 ± 3
Final washing	195	38 ± 3
Final bath	65	24 – 41
Process C-41 B/AP 71		
Developer	195	37.8 ± 0.25
Bleaching	180	38 ± 3
Fixing	240	38 ± 3
Stabilizing	47	38 ± 3
Stabilizing	47	38 ± 3
Stabilizing	47	38 ± 3
Process C-41 RA/AP 72		
Developer	195	37.8 ± 0.25
Bleaching	45	38 ± 3
Fixing	90	38 ± 3
Stabilizing	20	38 ± 3
Stabilizing	20	38 ± 3
Stabilizing	20	38 ± 3

The processes for minilabs, C-41 B/AP-71 and C-41 RA/AP-72, are significant in that they have shorter bleaching times. In the first process, bleaching is cut to 3 min by mixing the iron complexes of EDTA and PDTA (1,3-propylenediaminetetraacetic acid) instead of using iron(III) EDTA alone. In the second case, the use of iron(III) PDTA alone brings the bleaching time down to 45 s. The use of a thiosulfate – thiocyanate mixture shortens the fixing time to 90 s.

The topic of color negative film processing also includes processes for motion-picture films. These differ from processes for color negative still films in the sequence of baths and the compositions.

Color Negative Motion-Picture Film Processing. The commonly used process for color negative motion-picture film is the Kodak ECN-2 process [332]. It exists in two variants using different bleaching agents. The recommended process employs peroxodisulfate ("persulfate"), but this agent requires a bleach accelerator bath immediately upstream of the bleaching bath (see Table 4).

Table 4. Sequence of baths in color negative motion-picture processing

Bath	Processing time, s	Temperature, °C
Pre-bath	10	27
Backing removal	5	27 – 38
Color developer	180	41
Stop bath	30	27 – 38
Bleach accelerator ∗	30	27
Washing ∗∗	30	27 – 38
Bleaching bath (persulfate ∗, hexacyanoferrate(III) ∗∗)	180	38 ∗, 27 ∗∗
Washing	60	27 – 38
Fixing	120	38
Washing	120	27 – 38
Stabilization	10	27 – 38

∗ First variant.
∗∗ Second variant.

The accelerating agent, an isothiuronium compound, has the Kodak designation PBA-1. The second, alternative variant uses hexacyanoferrate(III) as bleaching agent (see Table 4). Because persulfate is reduced to sulfate, its presence in wastewater poses no problem, in contrast to hexacyanoferrate [333].

Color Positive Motion-Picture Film Processing. The ECP-2 A process introduced by Kodak is also commonly used here [334] (see Table 5). Again, there are two variants, which differ in the bleaching bath [335].

Table 5. Sequence of baths in color positive motion-picture film processing

Bath	Processing time, s	Temperature, °C
Pre-bath	10	27
Backing removal	2	27
Color developer	180	36.7
Stop bath	40	27
Washing	40	27
First fixing	40	27
Washing	40	27
Bleach accelerator ∗	20	27
Bleaching bath (persulfate) ∗	40	27
Bleaching bath (hexacyanoferrate) ∗∗	60	27
Washing	40	27
Sound track development	20	room temp.
Spray washing	2	27
Second fixing	40	27
Washing	60	27
Stabilization	10	27

∗ First variant.
∗∗ Second variant.

This process differs from the one used for motion-picture negative film because the optical sound track on positive film must be brought up in the form of a pattern of silver metal.

Sound Track Development. After the negative and the optical sound track have been exposed, development takes place. Unexposed silver halide is removed by fixing, and a bleaching step follows. Since bleaching takes place in the light, the newly produced silver halide is also exposed. A narrow roller then applies the thickened sound track developer to the edge of the film, converting the sound track back into metallic silver. A second fixing bath finally removes the residual halide. The silver is needed to carry the optical sound signal, because the audio cells in projection equipment (cesium photocells) are sensitive only in the infrared, where the absorption of the film dyes is not adequate.

5.3.2.2. Color Reversal Film Processing

As an example, the E-7 process disclosed by Kodak in 1977 for the processing of Ektachrome films is described [336] (see Table 6).

Table 6. Sequence of baths in color reversal film processing

Bath	Processing time, s	Temperature, °C
First developer	360	38 ± 0.3
Washing	120	33 – 39
Reversal bath	120	33 – 39
Color developer ∗	360	38 ± 0.6
Conditioner ∗	120	33 – 39
Bleaching bath ∗	360	33 – 39
Fixing bath ∗	240	33 – 39
Countercurrent washing ∗	240	33 – 39
Stabilizing bath ∗	60	room temp.

∗ With lights on.

The first development is performed with hydroquinone monosulfonate and 4-hydroxymethyl-4-methyl-1-phenyl-3-pyrazolidone (Dimezone S). The subsequent reversal bath includes reversal agent RA-4 [contains tin(II) chloride]. CD-3 is used as color developer.

Table 7. Sequence of baths in the RA-5 process

Bath	Processing time, s	Temperature, °C
Color developer	45	35
Bleach – fixing bath	45	35
Washing	22.5	25 – 30
Washing	22.5	25 – 30
Washing	22.5	25 – 30
Washing	22.5	25 – 30

5.3.2.3. Color Negative Paper Processing

Since 1986, the composition of color paper has been changing. While all papers made before that time had silver chloride – silver bromide emulsions, Kodak began marketing a paper type with a pure silver chloride emulsion in that year. The new type and its processing have been adopted by all manufacturers as a new standard. The compatibility principle remains in effect.

Because silver chloride emulsions can be developed much faster than emulsions containing silver bromide, the processing time can be made much shorter than before: 45 s at 35 °C (versus 3 : 30 min at 33 °C). The bleach – fixing time is also greatly shortened through a reduction in pH, i.e., to pH 6.0 by addition of acetic acid. The process for color negative papers with silver chloride emulsions bears the Kodak designation RA-4 and the Agfa designation AP 94. The published RA-5 process is described as an example [337] (see Table 7).

Washing is carried out as a countercurrent operation in a four-stage cascade. Stabilizing baths replace the washing step in minilabs; there are many formulas for these, and no standard exists.

The processing of the still-existent silver chloride – silver bromide papers differs greatly from the method just described in the bath times and, above all, in the developer formula. This process is designated EP-2 (Kodak) and AP 92 (Agfa) (see Table 8).

Table 8. Sequence of baths in the EP-2 and AP-92 processes

Bath	Processing time, s	Temperature, °C
Color developer	210	33
Bleach – fixing bath	90	33
Washing	180	25 – 30

The developer differs in several principal ways: It contains benzyl alcohol and much more potassium bromide, and as antioxidants it has more sulfite, with hydroxylammonium sulfate used in place of diethylhydroxylamine.

Large laboratories commonly use a variant of the process, with bleaching, washing, and fixing, instead of a single bleach – fixing bath. The ease of rejuvenating the bleaching and fixing baths and of desilvering the fixing bath are advantages where enough space for larger processing machines is available. This variant is available for both types of color paper.

5.3.2.4. Color Reversal Paper Processing

The processing of color reversal paper uses a developer with significant elements of color reversal film processing. The first development is done with hydroquinone sulfonate and Dimezone S (see Section 5.3.2.2); color development is with developing substance CD-3 and the development accelerator is Hs 104 (ethylenedithiodiethanol). The fogging treatment is replaced by a diffuse reexposure, and the color developer also exhibits a much lower pH (10.4 instead of 12.4) and contains benzyl alcohol. The bleach – fixing bath is largely the same as in color negative paper processing. A wide range of materials and processes are again compatible. The processes are designated R-3 (Kodak) and AP-63 (Agfa); see Table 9.

Table 9. Sequence of baths in color reversal paper processing

Bath	Processing time, s	Temperature, °C
First developer	75	38
First washing (2 stages)	90	35 – 41
Reexposure	not specified ∗	not specified ∗
Color developer	135	38
Second washing	45	25 – 41
Bleach-fixing bath	120	38
Third washing (3 stages)	135	25 – 41

∗ Diffuse reexposure is performed with a lamp located above inlet to developer tank.

5.3.3. Developing Equipment [28], [338]

Amateurs and small-scale users develop materials in plastic trays. To achieve consistent development results, especially of color materials, small-scale users also employ developing tanks, some featuring motor drive and automatic temperature control. Industrial operations, X-ray laboratories, and large-scale processors usually have automated developing equipment. Wet processing consists of three steps – development, fixing, and washing (black-and-white materials) – up to a maximum of nine steps (color reversal materials) and generally requires between 90 s (X-ray films) and ca. 40 min (color reversal films). In the usual processes, the temperature is between 20 and 40 °C. It must be held precisely constant, particularly in the case of color materials (± 0.2 °C). In special cases, rapid development within a few seconds is possible if elevated temperatures and diminished quality are acceptable. The photographic material and the developer must be kept in motion relative to each other by mechanical agitation, squeezing, or introduction of nitrogen, so that development will proceed in a uniform way. The exact processing conditions depend on the model of equipment and are specified by the maker of the photographic materials.

In order to obtain consistent results over large quantities and long periods of time, developing equipment must meet the following conditions:

1) Constant temperature
2) Constant residence times in the individual baths
3) Constant chemical composition of the baths
4) Uniform agitation
5) Little carryover of solutions from bath to bath

Figure 46. Continuous-flow film developing machine for a minilab
a) Film loading station with knives to separate film from cartridge; b) Tanks with developing baths and film transport units (racks); c) Hot-air dryer; d) Delivery of developed film, leader card first; e) Tanks for replenisher solutions (4) and spent baths (2)

The following types of equipment are used:

Plastic trays and tanks find use mainly for the processing of single sheets of B & W paper and film. *Developing tanks* can accomodate single sheets or roll films on spools. Motor drives for these devices can also provide uniform agitation, and the temperature can be held constant with water baths. In contrast to tanks, *developing drums* offer automation of movement and temperature control. They are used for processing of larger formats.

Developing tanks and drums have no replenishment devices to hold the chemistry of the solutions constant. The baths are used only once, and these types of equipment are therefore called "one-time" developing machines.

When large amounts of material are to be processed and the standards of processing quality and convenience are more rigorous, automatic developing machinery with mechanized transport of the photographic material is used.

In one class of machines, sheets or films are clamped to *hangers or frames* and transported through the baths. With appropriate hangers, single sheets and roll films of various formats can be developed consistently and safely in the same machine. These devices are therefore widely used. However, in large laboratories where there is a heavy flow of standard formats they are being displaced by continuous developing machines.

In continuous film developing machines, friction drives transport motion-picture films, spliced or individual still films through the tanks. In contrast to roller-transport machines (see below), these machines are not self-threading but require a leader strip or card (see Fig. 46).

The capacities of such machines are from 20 films per hour in minilab designs to 2000 films per hour in large-scale developing and printing plants. Modern film processes have a "dry to dry" time of ca. 8 min.

Roller-transport machines for films or papers have driven roll pairs that transport the photographic material through the baths without clamping. These devices are particularly well-suited to sheet films (such as X-ray films), single sheets, and short strips of film or roll paper (Figs. 47 and 48).

A special design is used for *roll-fed papers of limited length*. The roll pairs are widely spaced in their rack. For reliable conveyance of the leading edge from one roll pair to another, the paper is inserted in V-shaped (swallowtail) guides. This transport method is employed chiefly in the widely-used compact paper developing machines found in minilabs (see Sections 5.6.3 and 5.6.4). These machines, working in conjunction with a printer, have capacities of 500 – 2500 prints per hour; the processing time from exposure of the paper to the dry print is 4 – 5 min with the modern rapid process.

Conveyor-type paper developing machines, also called *roll-fed paper developing machines*, are used only for the development of paper in roll form. The leading edge of the paper is fastened to a clamp on the conveyor belt. These machines can be built with very large capacities (see Section 5.6.4). Up to six paper strips can be fed one beside another at a transport speed of up to 30 m/min. With six strips, the development capacity is ca. 80 000 prints (9 × 13 cm) per hour (see Fig. 49).

All automatic developing machines have thermostatically controlled bath temperatures. The solutions are continuously circulated and filtered. They are replenished in accordance with the area of photographic material processed. Doctor blades, air squeegees, or suction heads are used to prevent the photographic material from carrying over much of the solution from one bath into the next one or into the dryer. All these machines have integral warm-air or radiant-heat drying. The size and number of tanks depends on the processing width, dwell times, and processing speed. Special devices are available for silver reclamation and environmental cleanup of baths and wash waters.

Photographic baths, especially color developers. may contain toxic substances. Direct contact may result in inflammations and rashes, and inhalation of vapors can cause swelling of the eyes as well as allergic reactions. Developing equipment must therefore be designed and operated in such a way that direct contact with the chemicals is prevented and the vapors produced cannot be inhaled (exhaust fans or similar provisions). The instructions of the chemical manufacturers must be strictly complied with.

5.4. Silver-Dye Bleach Process

In contrast to chromogenic materials, silver-dye bleach materials in the unprocessed condition contain all the dyes needed to form the image. In processing, the portions of the dyes not required for the image are chromolytically decomposed and washed out.

Chemically, the process is based on the reduction of azo image dyes by metallic silver. Silver metal is produced, in an amount proportional to the exposure, in the first processing step; a classical B & W development. Next, in the strongly acidic bleach bath, the azo dyes are reduced by the silver and thus decomposed. Reduction can only occur if the bleaching bath contains strong ligands for Ag^+, which transform the silver into a strong reducing agent. In practice, iodide (or, less often, thiourea) is used; the product is then insoluble silver iodide (or soluble silver – thiourea complexes).

The dye bleach reaction can be represented as

$$R^1\text{–N=N–}R^2 + 4\,Ag + 4\,HI \rightarrow R^1\text{–}NH_2 + H_2N\text{–}R^2 + 4\,AgI$$

a) Loading section with paper unrolling and drive; b) Processing tanks; c) Drip tank with doctor blades; d) Hot-air dryer; e) Delivery section with paper winding; f) Endless conveyor belt to guide leading edge of paper

Since the azo dyes and the developed silver are both immovably embedded in the gelatin layers and thus cannot react directly with one another, suitable redox catalysts are needed to effect the reduction. The only agents used in practice are quinoxaline derivatives, which can be reduced to a reactive 1,4-dihydro form with consumption of two reduction equivalents. This 1,4-dihydro form is able to diffuse and reacts with the azo dyes, regenerating the quinoxaline derivative.

Silver-dye bleach materials have the following basic structure: A gelatin layer containing a cyan azo dye and silver halide that is sensitized in the red range is coated on an opaque or transparent support. Next, a green-sensitive silver halide emulsion with a magenta dye is applied, and on top of this a blue-sensitive emulsion containing a yellow dye is added. These layers are separated by pure gelatin interlayers in order to prevent unwanted long-range bleaching effects in adjacent layers. The yellow image dye protects to a certain extent the green-sensitive and red-sensitive emulsions against exposure in their intrinsic sensitivity regions (by blue light); the interlayer below the yellow layer may also contain an additional yellow filter dye for more complete suppression of such exposure.

The dyes are bisazo or trisazo compounds substituted with sulfo groups that are largely unable to diffuse through the gelatin. The amines produced from the dyes on bleaching are virtually colorless; they can diffuse in the gelatin and have relatively good solubility in water.

After exposure, these materials are *processed* in the following way: The negative silver images in the three emulsions are generated by a classical superadditive B & W developer. The next step is treatment in the bleaching bath, which contains the redox catalyst and a mild oxidizing agent (an aromatic nitro compound) along with ca. 0.5 M sulfuric acid and ca. 0.1 M potassium iodide. The nitro compound competes with the dyes as a reaction partner for the reduced catalyst. It limits the lifetime and range of the reduced catalyst and thus blocks interlayer effects, even when the interlayers are thin, and also ensures the complete oxidation of excess silver. Next the silver compounds are removed in a rapid fixing bath. Finally, the material is washed to dissolve away any dye fragments that have been left behind in the emulsions.

The result is a positive copy of the original. Since the absorption maxima of the image dyes roughly coincide with the sensitivity maxima of the respective silver halide emulsions, silver-dye bleach materials have only modest sensitivity and are therefore used chiefly as print materials on opaque or transparent supports for displays. The outstanding antihalation effect of the image dyes yields a very high sharpness, therefore silver-dye bleach materials are used as microfilms. The azo dyes used to form the image afford high light stability.

Figure 50. Silver-dye bleach process
a) Original; b) Light transmitted or reflected by original; c) Interlayers; d) Base; e) Emulsions with developed silver; f) Emulsion layers after bleaching and fixing; g) Copy of original for viewing by reflected or transmitted light

The problem of unwanted secondary absorptions of the dyes, chiefly the secondary blue absorption of the magenta dye, is corrected by *self-masking techniques* in modern silver-dye bleach materials. The yellow dye at a given point in the image is bleached in proportion to the secondary blue absorption of the magenta dye present at the point. This self-masking technique is based on a supplementary layer beneath the yellow layer, in which the silver image negative to the green exposure is developed. The corresponding fraction of the yellow dye is then rendered colorless by long-range bleaching in the bleaching bath. The silver dye bleaching bath is shown in Figure 50. Other general descriptions of the silver dye bleach process are given in [339–341]. *Trade names* include Ilfochrome Classic, Ilfochrome Rapid.

5.5. Dye Diffusion Processes

The *Technicolor process* for motion-picture film copying, now obsolete and still in use only in China, was based on the successive transfer of three positive separation images to a mordant layer. It was thus a predecessor of the image-forming system used in instant photography. The same holds for the Kodak dye-transfer process.

5.5.1. The Polaroid Instant Photography Process

In 1963, Polaroid brought out Polacolor instant film; thus the transition was made from instant B & W photography, which used the silver halide diffusion process, to instant color photography by dye diffusion [342] (see Fig. 51 A).

In dye diffusion [343], the photographic process causes a different diffusivity of the various dyes or dye precursors that form the image. Diffusion starts at the beginning of development and ends at roughly the same time as silver development is complete; i.e., when a drop in pH in the stack of layers is induced.

Of the many chemical systems that have been described for the production of color prints by the dye-diffusion method, only a few have been turned into commercial materials. All use the principle of subtractive color mixing and are thus fundamentally different from the additive processes and for instant color transparencies or instant color films.

Instant materials employ either a *two-sheet* (*peel-apart*) *system* (see Fig. 51 A), in which the negative sheet and the image-receiving sheet are united for the dye transfer, or a *single-sheet* (*integral*) *system* (see Fig. 51 B), in which the image-recording part with the image-generating chemicals, the processing chemicals, and the image-receiving part are integrated.

Commercial materials derived from Polacolor II, the improved version of Polacolor (large formats, television screen recording, identity

Figure 51. Schematic layered structure of Polacolor instant film (A) and SX 70 integral film unit (B)

photographs), are peel-apart materials. Single-sheet systems are predominantly used in amateur photography.

All integral materials are covered by basic patents held by Polaroid and are extraordinarily complicated. Obtaining an image whose quality is comparable to that of conventional color photographs requires not only the photographic emulsion layers proper but also a number of auxiliary layers, which control the process and compensate for the inherent temperature dependence of the system.

The image dyes (yellow from the blue-sensitive emulsion layer, magenta from the green-sensitized layer, and cyan from the red-sensitized layer) are fixed in the image-receiving layer by a mordant and viewed against a white background. Polymers with cationic groups serve as mordants. The dyes are held in place by ionic bonds.

Currently the time required to obtain a picture is in the range of 1 – 3 min, depending on the temperature. An acidic polymer layer stops silver development and dye diffusion. It is separated from the other layers by at least one timing layer consisting of an alkali-sensitive polymer. The acidic layer abruptly becomes alkali-permeable only after the proper action time. These layers can also contain additives to prevent both fogging and subsequent increases in density.

The processing chemicals are embodied in a highly viscous, strongly alkaline paste, which is squeezed out of a pod by rollers and spread through the integral film unit as a film when the unit is removed from the camera. Excess paste is collected in traps. The correct, uniform thickness of the paste film is ensured by the stiff backing, spacers, and image masks.

The Polaroid Image System (U.S. Brand Name: Spectra) The Polaroid Image System [344] (see Fig. 52) was developed from the SX-70 system (brought out in 1971) and consists of the Impulse series of cameras and P-600 Plus film.

The exposure and viewing directions are the same. The transferred image is examined through the backing, against the white-pigmented background of the developer paste. The image-generating part must therefore be rendered opaque from the moment is leaves the camera until the image-production time has

passed. This is done by a decolorizing indicator dye in the processing paste.

The Polaroid system operates with negative emulsions. For magenta and cyan, the reversal of the image is achieved through the use of dye developers, which were used in the SX-70 system and its predecessors. The *magenta* (Fig. 53 A) and *cyan dye* (Fig. 53 B) *molecules* [345] contain hydroquinone residues and therefore act as developers: they are dissolved by alkali and have the ability to diffuse. By transferring electrons to the auxiliary developer, which actually develops in silver halide, the dye developers in exposed regions of the image are converted to insoluble and immobile quinoid products. Only the unoxidized portion of the dye is transferred to the image-receiving layer.

Figure 52. Schematic layered structure of a Polaroid image film unit

The *yellow image* in Polaroid P-600 film is based on a dye-releasing compound working on the argentolytic principle [346]. In other words, the compound reacts with silver ion to form a silver complex and release the yellow dye. This system, in which the silver ions of the undeveloped grains are utilized, also works to reverse the image. Diffusion control ensures that only dissolved silver ion from the blue-sensitive layer can react with the dye-releasing compound, a nondiffusing thiazolidine compound.

5.5.2. Kodak and Fuji Instant Photography Processes

Kodak PR-10 System. The Kodak PR-10 system [347], which also used integral film units, was introduced in 1976. Fundamentally new features that characterized the system were the use of nondiffusing dye-releasing compounds with developer properties (from which the highly diffusible image dyes – simple anionic monoazo dyes – were released by oxidation and subsequent hydrolysis) and the use of unfogged direct positive emulsions for image reversal. The dye-releasing compounds were 4-sulfonamido-1-naphthols [348]. The system underwent a number of improvements, which led to better shelf life and higher speed (ISO 320). The Kodamatic Trimprint system (1983) provided for the subsequent separation of the transfer red dye image from the negative. After losing a patent suit to Polaroid, Kodak withdrew the instant photography system from the market in 1987.

The Fuji System F 10 Fotorama. In 1981, Fuji brought out an *integrated* instant-picture material compatible with the Kodak PR-10 system (format 4×5 inches = 10.15×12.7 cm) but utilizing different dye-release chemistry [349]. The system was intended for the Japanese domestic market.

A further development of this system is the Fotorama system with F 1-800 G *peel-apart* film, which is for sale in Japan. Since the abandonment of instant photography by Kodak, there is no need for compatibility with the Kodak system. The Fuji instant film, like that in the Kodak system, uses negative-working dye-release chemistry.

The *ortho*-sulfonamidophenol dye releasers in the Fuji material (see Fig. 54), like the *para*-sulfonamidoaphthols in the PR-10 system, are strong reducing agents, which are converted

Figure 53. Dye developers in the SX-70-Time Zero and Polaroid image unit
A) Magenta dye developer; B) Cyan dye developer

to alkali-labile *ortho*-quinonesulfonylimines after oxidation. Because of the high alkalinity of the processing paste, the dye group – which is attached to the quinoid dye-releaser oxidation product by the sulfonylimine group – is split off from the nondiffusing carrier by hydrolysis, thus becoming diffusible (see Fig. 55).

The negative transfer characteristic of the *ortho*-sulfonamidophenols means that the required image reversal must be accomplished through the emulsions. Remarkable advances in emulsion technology have now made it possible to use high-speed, unfogged direct positive emulsions of the internal- center type (rated speed: ISO 800). These emulsions are not developed after exposure (see Section 3.1.1). Instead, the action of an incorporated hydrazine derivative in the developer causes subsequently developable reduction centers to form on unexposed grains. In this way, high dye-transfer densities are achieved in the unexposed regions, while exposed portions of the image remain virtually transfer-free. Electron transport between the emulsion and the nondiffusing dye-release compound is implemented by Phenidone-type auxiliary developers.

The integral film unit is taken out of the camera immediately after exposure, passing through a pair of rolls that rupture the pod and spread the paste into the space between the cover sheet and the image sheet (i.e., later separation of integral sheet). Unwanted re-exposure through the cover sheet is prevented by carbon-black in the paste. In contrast to the Polaroid system, the image-receiving layer is located on the back of the film unit. The image is viewed against a white-pigmented layer (containing titanium dioxide), which in turn is backed by an opaque carbon-black layer. The Fuji instant picture also has auxiliary process- control layers in the cover sheet.

The image-receiving part is structured as in "stripping film"; the transfer image is separated from the image-generating part after the process is complete.

Figure 54. Dye-releasing compounds of Fuji instant color film Fl-800 G

Figure 55. Dye-releasing mechanism of Fuji instant color film Fl-800 G

5.5.3. Agfachrome Speed and Ektaflex

Eastman Kodak, Agfa – Gevaert, Konishiroku, and Fuji have proposed newer dye-release systems [350–353] in which the bond between the dye and the nondiffusing carrier is broken by reduction instead of oxidation. The electron-donor compound used as reducing agent is accordingly consumed by the silver halide in regions where development takes place and by the dye-release compound in the unexposed regions.

These dye-release systems are positive-working and yield fog-free transfers when the process of silver development is ensured. The best way to do this is by alkali-labile blocking of the electron-donor compound.

5.5.3.1. Agfachrome Speed

The sheet material Agfachrome Speed [354] was introduced in 1983, simultaneously with the Copycolor graphic-arts material (→ Imaging Technology, Chap. 2.2.3.2.), but is no longer on the market. Agfachrome Speed was a print material for the home laboratory. It used dye-releasers of the quinone methide type, with which brilliant prints could easily be made from transparencies. The material was exposed through the backing but viewed from the emulsion side against

a white-pigmented background. Processing was done by immersing the material in an alkaline activator.

5.5.3.2. Kodak Ektaflex PCT [355]

Kodak has not brought out any material with the new dye-release systems. Both the negative version (1981) and the reversal version (1982) of the Ektaflex PCT peel-apart print material utilize the negative-working dye-release chemistry of the PR-10 system, i.e., the Ektaflex PCT Reversal Film in combination with direct positive emulsions. Both materials have now been withdrawn.

5.5.4. Additive Instant Color Photography Systems

Additive instant color systems do not produce and transfer a dye image. Instead, a threecolor additive linear screen, in the primary colors blue, green, and red, is overlain by a silver positive to form the image. The positive is obtained by silver halide diffusion in a receiving layer. Accordingly, the projected brightness of an additively produced instant picture is roughly two-thirds less than that of a conventional transparency. The technical challenge of the system lay in the costly process of obtaining an extremely fine linear screen from dyed, dichromated gelatin in three layers along the optical path; i.e., virtually invisible when projected [356].

Figure 56. Schematic layered structure of a Polachrome film

5.5.4.1. Instant Color Transparency [357]

Two 35 mm transparency films, Polachrome CS (introduced in 1982, speed ISO 40) and Polachrome HCP (a high-contrast film), use an additive linear screen having 394 line triplets per centimeter (see Fig. 56). They are exposed through the base and the screen. The negative part is stripped off in the processor. The transparencies are put in slide frames and ready for projection immediately after they are processed.

5.5.4.2. Narrow-Gauge Instant Color Film [356]

The Polavision narrow-gauge film system (Super 8 format) consisted of player, camera, and film cassette. The film had a linear screen with 590 triplets per centimeter. The structure was not altered in processing; the individual image, with low light-transmitting power, was projected through a superimposed negative with extremely low covering power. Polavision therefore remained a specialty material for limited applications. It was taken off the market in 1988.

5.6. Making Color Prints [28], [338]

In black-and-white photography, the illumination in the printer must be matched to the sensitivity of the print material and the density of the original, such as a negative. In color printing, the illumination must be separately controlled for each of the three emulsion layers in the paper (sensitive to blue, green, and red) in order to obtain a print of the correct density without color distortion. The printing light is controlled as the color and exposure by the additive or subtractive process. Correct illumination can be determined empirically or with the help of measuring devices. Color prints can be produced from color negatives or, as direct positive prints, from transparencies or color prints (on color reversal paper).

5.6.1. Printing Processes

Additive Printing Process. The basic principle of the additive printing process is the separate exposure of each emulsion in the print material through filters in the additive primary colors

blue, green, and red. The three exposures can be performed one after another by inserting the three printing filters in the ray path one by one, or simultaneously by combining the properly filtered light from three printing lamps into a single beam.

The light in each of the three color channels is precisely metered to the process in one of two ways: at constant intensity and variable exposure time, or by spectrally neutral brightness modifications. For example, if the first positive print made from a color negative comes out too yellow, the exposure time or the intensity of the blue light must be reduced so that the blue-sensitive yellow emulsion receives less exposure.

The additive printing process has the advantages that it is easy to follow, the light control is cleanest from the spectral point of view, and the printing light can be matched to the absorption of the negative dyes and the sensitization of the positive material. Its principal drawback is the low intensity of the light passing through the additive filters, which leads to excessive exposure times and the necessity of using high-output printing lamps.

Subtractive Printing Process. In the subtractive process, the desired color balance is achieved by placing subtractive filters (yellow, magenta, cyan) in the projection beam of the printing equipment. For example, if a positive print made from a color negative without filters turns out too yellow, a yellow filter of suitable density is inserted to stop part of the blue light. The blue-sensitive yellow emulsion now receives less exposure, and the yellow in the print is de-emphasized. For fine control, either a color filter of the proper density can be selected or a color filter of maximum density can be inserted partway into the beam. In the second case, however, it is necessary to ensure especially good mixing of the light downstream of the filter.

The most commonly used method of subtractive exposure is a "white" main exposure followed by a subtractive second exposure. The first step is an exposure with white light, which contains the blue, green, and red components. When the exposure in a certain color is sufficient, the subtractive filter blocking that color is pivoted into the beam. For example, if the blue exposure is finished first, a yellow filter is inserted which blocks the blue light but lets the green and red light through. A similar procedure is followed when the exposure of another color is sufficient; that is, a second substractive filter is pivoted into the beam along with the first, so that the only light used for continued exposure is the color passed by these two filters in series. For example, a combination of yellow and cyan filters is transparent only for the color green, and green can be finally blocked by adding the magenta filter. For the principles by which the pivoted or sliding filters are controlled, see Section 5.6.2.

The subtractive printing process has the advantage of relatively simple design and high light intensity, but it is complicated by the secondary absorptions of most color filters. Most color printing machines use the subtractive method.

5.6.2. Exposure Control

Because the eye is more sensitive to slight differences in color than it is to density differences, the color matching in the print must be performed with special care, and for this purpose the correct color exposure must be determined precisely.

The simplest but most laborious method is to make test prints (test strips) with various filter arrangements, develop them, and select the combinations that give the optimal color match. When quality standards are high, these operations must be repeated several times. This primitive method is now used only in special cases. All modern color printers employ exposure control based on optical measurement of the negative and calculation of the quantities of blue, green, and red light needed for exposure of the paper. In simpler machines, the integral transmission densities of the negative in the colors blue, green, and red are measured, and on the basis of the values found the light intensities in the three colors are controlled in such a way that all three emulsion layers in the print material produce about the same color density. This method is based on the assumption that all three primary colors are represented in equal strength in an average amateur picture (neutral gray principle). Together with supplementary conditions for overexposed and underexposed pictures as well as large variations in color and density from region to region inside the negative, this principle results in almost 90 % color-correct prints. The remain-

der are reprinted with individual correction. A simplified version of this kind of machine is the *color analyzer*.

In color printers that must satisfy higher standards, the image analysis is carried out with much greater precision. The negatives are broken down into 100 or more pixels, and the densities at the individual scan points are measured in the blue, green, and red regions (*color scanner*). A complex analysis of these local color and lightness values permits a much more exact determination of the quantities of light needed for printing.

As in the integral method, however, data on typical printing properties of films from various manufacturers must be determined empirically and entered in a program (printer memory), so that the proper exposures can be calculated from the data for the given film together with the measurements on the negative. Films now on the market have the film type coded on the edge in machine-readable form (DX code) so that the type can be determined automatically.

The state of the art in measurement and analysis is *total film scanning*, in which the measurements on all negatives of the film being printed are lumped together and analyzed. In this way, statistical methods can be applied to determining the photographic properties of the film (film-specific data) separately from incidental features of the individual negatives (image-specific data).

This procedure not only permits the first-class reproduction of all exposures from a film, but also the processing of all film types from all manufacturers without preprogramming (one-channel processing). For average amateur negatives, the yield of prints which are correct with respect to color and brightness is ca. 99 % with this technique.

5.6.3. Types of Color Printers

The classical darkroom enlarger is currently used only for special tasks. Virtually all color prints are made on color printing machines, which can be classified by application as high-capacity, universal, special-purpose, and minilab printers.

The principal use of *high- capacity printers* is usually the fully-automated mass production of prints from freshly developed amateur films (first print). These machines have film scanning systems and offer capacities of 10 000 – 20 000 prints per hour. Photographic paper and films must be supplied in strip form already wound on spools; films are spliced together before develop-ment. These machines can make prints in formats up to 13 × 18 cm.

Universal printers are also used in printing amateur pictures. They can handle special jobs that do not lend themselves to automated processing (roll films, detail enlargements, mini-posters, etc.). Universal printers feature simple integral measuring systems and operate rather slowly, because the technical setup depends on an operator. These printers can print on the appropriate papers from both negative films and reversal films (transparencies).

Special-purpose printers are related to the universal type but can handle wide papers (up to 75 cm); most of them have a wide range of continuously variable enlargement ratios, which makes them suitable for all kinds of special jobs. Such a printer requires an operator and is used mainly for professional photographic work.

The *video printer* is a variety of special-purpose printers. In this device, the exposure process is first electronically simulated, and the result is displaced on a color monitor. The operator can modify the monitor image until its brightness and color are satisfactory. Because the printer can be controlled in such a way that the print exactly matches the display, a high-quality print can be made without subsequent costly testing.

The *minilab printer* (Fig. 57, see also Section 5.6.4) is directly connected to a paper developing machine. This type of printer is related to the universal type, but the higher-quality models have modern negative scanners such as those in high- capacity printers. These machines are designed for capacities of ca. 500 – 2000 prints per hour. By virtue of the expensive measuring instruments, even photographically untrained personnel can achieve very good print quality on a first attempt.

The applications of *digital printers* fall between those of universal and special-purpose printers. Also called *cathode ray tube (CRT) printers* or *laser printers* (depending on their operating principle), these devices represent an entirely new generation of color printers. While conventional color printers have the capability of

Figure 57. Minilab printer with paper developing machine
a) Paper supply cassette; b) Paperdeck; c) Variable-ratio objective and negative carrier; d) Color scanner with illumination system; e) Printing lamp house with exposure filters; f) Tanks with developing baths and roller transport system with V-guides; g) Hot-air dryer; h) Print cutter; i) Print stacker

modifying only the brightness and color of the print, the digital printer can also vary the contrast and color saturation as well as enhance the preceived sharpness. These advantages are achieved by placing the original (transparency or negative) in a high-resolution color scanner where it is broken down into several million image points (pixels). The pixels are stored electronically in "image memories"; a computer used to modify them in accordance with certain criteria (image processing) leads to the features just cited. The pictorial outcome of these operations can be continuously monitored on a color display. Finally, the signals representing the manipulated pixels control the intensity of a laser beam or of the electron beam in a CRT, which exposes the light-sensitive material (e.g., normal color negative paper) point by point in order to create the print.

Once the original has been scanned, the image exists in the form of electrical signals anyway; hence the electronics could also be supplied with external signals representing any electronically stored image. Such an image can be optimized and printed as described above. This procedure is significant chiefly in conjunction with electronic still photography (still video camera).

Another new picture-storage medium that has become commercially established is the *Photo Compact Disc* (*Photo CD or PCD*). The PCD is a plastic disc, similar to an audio CD, on which up to 100 color negatives or color transparencies (size 24×36) can be stored by means of a high-resolution optical scanner. The pictures are retrieved by a PCD player and can be used for various purposes. For example, they can be displaced on a television screen or used in preparing layouts in desktop publishing and – in combination with image processing – for producing professional graphics.

5.6.4. Laboratories for Amateur Color Photographs

The mass production of amateur photographs in large laboratories involves the logging, tagging, and splicing of the films and their development in continuous-flow developing machines. After development, the photos are printed on color paper in fully-automated printers. The exposed roll

paper is developed and cut. The finished pictures, along with the films, are shipped back to the outlets where the films were accepted. The centralization and automation of photo production has led to a steady decline in the price of amateur pictures since the 1960s despite increasing wages and material costs.

Since the end of the 1970s, an alternative to mass production in the large laboratory has been gaining importance: the *minilab*. The minilab, usually an in-store operation in a good shopping location, is a small laboratory set up for film development, printing, and paper development and having a capacity of 150 – 500 films per day. The equipment for such an operation is specially designed for this application, combining compactness with advanced technology (see Sections 5.3.3 and 5.6.3). These minilabs are attractive to customers because most offer one-hour service and the amateur can personally discuss the photographs with the laboratory personnel.

5.6.5. Copying of Motion-Picture and Television Films

Internegatives and interpositives from motion-picture and televison films are also made by the additive and subtractive methods. Because film transport is uniform, however, each frame must receive the same exposure time, so that the density and color can be controlled only through the filtering and the intensity of the copying light. Two approaches are used in determining the proper filters or intensity: test copies are made from the beginning or end of each scene, or video analyzers are employed.

The duplicates themselves are made by the additive or the subtractive process. The most commonly used *additive printers* have an exposure system in which the light from a copying lamp is split into the three primary colors blue, green, and red by dichroic mirrors. Each primary color beam has an electrically adjustable light-damping element ("light valve") inserted in it. After passing through the light valves, the three beams are reunited and guided to the printing station. Whenever the scene changes, a message carried on the original initiates a readjustment of the light valves in accordance with a program stored on punched tape or electronically. In *subtractive* printing, the color and gray filters needed for each scene are mounted on a black paper strip with punched holes and automatically brought into position scene by scene.

In the interest of consistent quality in the printing of television and motion-picture films, sensitometric monitoring of the process is particularly important. An immersion liquid can be used at the printing station in order to prevent loss of sharpness and contamination.

6. Photographic Properties and Their Measurement

This chapter describes the properties that govern the quality of photographs. "Quality" is thought of in very broad terms. In addition to properties such as tonal reproduction, sharpness, granularity, and color reproduction, the discussion also includes the stability of films and images. Improvements in stability, particularly of color materials, has been the focus of intensive research by manufacturers of photographic materials in recent years. The methods used to measure the properties cited are also described.

6.1. Sensitometry and Densitometry

*Sensitometry*currently means the study of the relationships between the developed photographic image and the exposure. Formerly, this term was restricted to determining the sensitivity of photographic emulsions. Scientific sensitometry was founded by HURTER and DRIFFIELD [358]. A detailed summary of sensitometric methods can be found in [34], [36]. *Densitometry* is the measurement of optical density in transmission or reflection.

6.1.1. Optical Density

The image as perceived is created by variations in the absorption of light in the emulsion, corresponding to the quantities of silver or dye formed after exposure and development. If Φ_0 is the radiant flux incident on a developed, transparent emulsion and Φ_τ is the radiant flux transmitted

after absorption, then $\tau = \Phi_\tau / \Phi_0$ is the transmittance and $D_\tau = -\log \tau$ is the transmittance density.

Similarly, for photographic papers viewed in reflected light, $\rho = \Phi_\tau / \Phi_0$ is the reflectance and $D_\rho = -\log \rho$ is the reflectance density.

In photographic papers, incident radiation is reflected in the baryta coating or, in resin- coated papers, in the titanium oxide- containing resin films; a portion of the incident radiation reaches the fiber base of the paper before being reflected. As it passes through layers containing silver, the light is scattered. The scattering depends on the size and structure of the silver grains. The measured density or diffuse density is therefore a function of the geometry of the measuring setup (see Section 6.1.3). The spectral makeup of the radiant flux remains virtually unchanged on passage through silver layers, which are thus said to be gray. In contrast, the absorption of the measuring beam in color emulsions is strongly dependent on wavelength. With monochromatic light of wavelength λ, the measured spectral density is symbolized by D_λ and the spectral transmittance by τ_λ (the reflectance by ρ_λ). With light having a known spectral distribution Φ_λ and a detector having a known sensitivity s_λ, the *integral density* D_i measured over a range of wavelengths is given by

$$D_\mathrm{i} = \log \frac{\int_0^\infty \Phi_\lambda e_\lambda s_\lambda \mathrm{d}\lambda}{\int_0^\infty \Phi_\lambda e_\lambda s_\lambda \tau_\lambda \mathrm{d}\lambda}$$

where Φ_λ is the incident flux at wavelength λ, e_λ is the relative spectral efficiency of the entire optical system, s_λ is the relative spectral sensitivity of the detector, and τ_λ is the transmittance of the specimen at wavelength λ.

The scattering power of color emulsions can generally be neglected in transmission measurements, and so the geometry is not critical. The same does not, however, hold for color materials viewed in reflected light (see Section 6.1.3).

Integral color densities are found by measurements on the complete assembly of emulsions in color materials. For routine measurements, optical filters in the colors blue, green, and red (corresponding to the three subtractive colors yellow, magenta, and cyan) are placed ahead of the material in the beam and the filter densities are determined. Films and papers whose images are examined with the human eye must be evaluated by measuring the *visual optical density*; this is performed with a detector whose relative spectral sensitivity matches that of the eye and with a beam of light whose spectrum corresponds to a temperature of 3000 K, i.e., tungsten light. In the case of negative films, the detector characteristic is matched to the spectral sensitivity of the print material. The density measured in this way is called the *printing density.*

Analytical densities are the color densities of individual emulsion layers. In practice, direct measurement of analytical density is possible only for the manufacturer of the photographic material. The spectral analytical density is defined by analogy with the spectral density (see above). In the assessment of the color-reproducing ability of a photographic material, the colors of the individual layers are combined into a hue with a neutral gray appearance, whose density is measured as the visual optical density. Figure 58 shows the integral (total) spectral density (curve a) for a specimen with a visual optical density of 1.0. The spectral analytical densities of the three layers are plotted as curves b, c, and d. The three dye layers are superimposed to form a gray tone "metameric with true gray." The spectral absorptions of individual dyes are not restricted to the regions of their "defined" colors, because there may be large secondary absorptions at nearby wavelengths; i.e., major color densities are distinguished from minor color densities. In the example of Figure 58, the measured integral density in the major absorption region of the yellow layer (436 nm) is due to three contributions: the analytical major color density (64 %), the analytical minor color density of the magenta layer (19 %), and that of the cyan layer (17 %). The minor color densities degrade color reproduction through chroma losses and hue shifts.

The analytical major color densities of the individual dyes that add to give the visual gray density are called "equivalent neutral densities." If the integral densities are measured in the region of the major color densities of the three layers with appropriate narrow- cut filters, both the analytical densities and the equivalent neutral densities can be calculated from the results [359], [34].

Figure 59. Sensitometric density curve for negative film (H = exposure in lux · s)

6.1.2. Characteristic Curve and Evaluation

If the optical density is plotted versus the logarithm of exposure $H = E \cdot t$ (in lux · s), the characteristic curve is obtained. This curve goes back to Hurter and Driffield [358] and remains the most important way of presenting sensitometric results. A characteristic curve always has a typical shape. For a photographic material that yields a *negative image* of the object represented (Fig. 59), the curve begins at low (not yet effective) exposures, showing a density called the fog density. Then comes the toe (underexposed region). The next part of the curve is nearly a straight line (normally exposed region). The shoulder represents the region of overexposure and is followed by the maximum density. As exposure increases further, the density may fall off again. This portion of the curve represents solarization. For a photographic material that yields a *direct image* of the object (e.g., a reversal film or an instant-picture material; see Fig. 60), a high density corresponds to the region of low "sub-toe" exposure, and the characteristic curve is inverted relative to that of the negative material.

Figure 60. Exposure range of a reversal film
a) Maximum exposure range; b) Exposure range of normal objects; c) $\Delta \log H = 0.3$, that is $\pm 1/2$ stop

In practical sensitometry, the density curves are described in terms of parameters that convey information about the photographic properties. The most important is the exposure necessary for a stated density; this is equivalent to the position of the whole curve relative to the exposure axis. It determines the *sensitivity,* whose measurement is described in detail in Section 6.1.3. The slope of the characteristic curve [$dD/d(\log H)$] is a measure of how relative exposure differences are transformed into density differences or density contrasts. The slope is at a maximum on the straight-line portion of the curve. This maximum value is called the gamma (γ) and is a measure of gradation. In emulsion types that have a more S-shaped characteristic with no straight-line portion, the gamma is replaced by the slope of the secant passing through two points significant for image formation (this is sometimes called beta). The gradation of a photographic material increases with the development time, among other factors. Curves illustrating this relationship are called contrast index curves.

Depending on the numerical gradation value, materials in practice are said to be soft-, flat-, or weak-working ($\gamma \approx 0.4$) on the one hand or steep- or hard-working on the other. "Normal" gradation values are 0.6 – 0.8 for negative films and 1.5 – 2.5 for papers.

Fog, gradation, and maximum density define the range of exposure values that can be reproduced as differentiable densities. The brightness range of a scene is the ratio of the lowest to the highest luminance measured in the image plane of the camera. It is the ratio of luminous flux between the darkest and the brightest part of the scene (called object luminance ratio by GOLDBERG [37]), corrected for the contrast-reducing effect of camera flare. According to studies by JONES and CONDIT [360], landscapes in full sunlight have a luminance ratio between 1 : 10 and 1 : 40; portraits with black and white clothing, from 1 : 30 to 1 : 50; interiors with bright windows, from 1 : 100 to 1 : 1000; and printed illustrations, from 1 : 4 to 1 : 10.

Figure 61. Exposure range of a negative film
a) Maximum exposure range; b) Exposure range of normal objects; c) $\Delta \log H = 1.8$, i. e., ± 3 stops

The luminance ratio is specified in logarithmic units on the exposure axis of the characteristic curve. An "average" object corresponds to 1.3 log units (1 : 20). A photographic material offers some freedom, depending on the shape of the characteristic curve, in the selection of the mean exposure (exposure latitude) so as to bring a given luminance ratio inside the useful range of the density curve. In the example of Figure 61, the maximum useful exposure range of a B & W negative film is ca. 3.1 log units. The exposure latitude is calculated as follows: maximum exposure range − exposure range of normal objects; i.e., 3.1 − 1.3 = 1.8, i.e., ± 0.9 log units or ± 3 stops. As Figure 60 shows, the exposure latitude of a B & W reversal film is only ± 0.5 stop. The maximum exposure range and thus the exposure latitude are still smaller for papers on account of the lower maximum density.

Figure 62. Characteristic curves of a color reversal film A) Neutral; B) Speed mismatch, yellow-red- cast; C) Higher red contrast (density)

The sensitometric behavior of color photographic materials is represented by three color-density curves corresponding to the three primary colors. The parameters listed in the preceding section also apply to color materials, but now it is necessary to consider the interaction of the three dye layers; hence, there are three times as many parameters. As already pointed out, a color material under given exposure conditions should reproduce gray object colors as a total density that appears gray to the eye or in the positive material. If the nominal "equivalent neutral" filter densities are known, then the position of

the color-density curves indicates whether this condition is satisfied. For clarity, it has been assumed in Figure 62 A that parallel color-density curves represent a neutral-gray density curve. A departure from this nominal shape corresponds to a color imbalance (cast) in the material. For example, if the color densities in the magenta and the cyan are relatively low, the image will display a yellow-red cast (Fig. 62 B). If the gradations of the three color curves do not match, the color imbalance may differ in the underexposed and overexposed parts of the curves, and indeed as a rule the casts are colorimetrically opposite. If the cyan curve has too high a slope (Fig. 62 C), the image will show a red cast at low densities (highlights) but a cyan cast at high densities (shadows). The film "tilts" from red highlights to cyan shadows.

Figure 63. Filters
A) Continuous wedge; B) Step wedge, density difference = 0.15

6.1.3. Measurement of Density

The material to be tested is first exposed in a *sensitometer* with regularly increasing quantities of light. Either the time can be held constant and the illuminance varied (*intensity-scale densitometer*) or the illuminance can be held constant and the exposure time varied (*time-scale sensitometer*). Because the reciprocity law does not hold in photography with visible light (Schwarzschild effect), the two methods do not give equivalent results. Most sensitometers now in use are of the intensity-scale type. The light is attenuated by neutral-gray filters; such a filter consists of a glass flat with a silver, graphite, or dye layer. Filters of two types are used: discrete patches with constant increments of density (step tablet or step wedge with density increment 0.1, 0.15, or 0.3; see Fig. 63 A) or a wedge with continuously increasing density (0.1, 0.15, or 0.3 density difference per centimeter of length; see Fig. 63 B). Density increments of 0.1, 0.15, and 0.3 correspond to increases in exposure by factors of 1.26, 1.41, and 2. The exposure time is usually set by means of a falling-plate shutter or a slot moving at constant speed in front of the gray wedge. The sensitometer light source must be arranged in such a way so as to illuminate the wedge uniformly, and must be calibrated and constant in color temperature and intensity.

The exposed "sensitometer strip" is then carefully processed in the prescribed baths. The reproducibility of development is a crucial factor in the precision of the whole process.

Instruments for measuring optical density are called *densitometers.* The basic elements of such a device are a light source as near to a point source as possible, an aperture for the object being measured, a photoelectric detector (photocell or photomultiplier), a readout for the (measured) density, and a filter (several in the case of color materials) serving to match the spectral distribution of the measuring light to the detector sensitivity. The conditions for the standard determination of the optical density of transparent layers are set forth in ISO 5/3 [361]. For the measurement of diffuse density in B & W films, the specimen must be illuminated with parallel light and the entire half-space behind the specimen must be measured with an Ulbricht sphere or a diffuser between the specimen and the detector.

According to the reversibility principle of ray optics, this arrangement can be changed to diffuse illumination and measurement in parallel light.

To measure the color density of *color films,* filters matched to the three principal absorptions of the dye layers are used. Such filters

include interference filters for wavelengths of 435.8, 546.1, and 643.8 nm, or the Kodak Status A, M, or D filters, depending on the type of photographic materials being tested (see below).

Kodak Status A Reversal film, print films
Kodak Status M Color negative film
Kodak Status D Reflection densities, paper

Visual optical densities or printing densities are determined in accordance with ISO 5/3 and 5/5 [361] respectively, which establish numerical conditions relating to the color temperature of the lamp and filter versus the wavelength.

In *reflected-light densitometers,* a definite geometry is required for the measurement of reflected density, because of surface scattering effects [362].

Densitometer designs fall into two groups: direct-reading and comparison instruments. *Direct-reading instruments* use analog or digital instruments to measure directly the output current of the photoelectric detector. The logarithmic density is obtained from the reading with specimen in relation to the reading with no specimen in the beam. Light sources for direct-reading densitometers must be highly constant and detectors must be highly reproducible, but instruments on the market today easily meet these standards.

In *comparison instruments,* the detector serves as a null indicator. Behind the filter set, the measuring beam is split into a sample beam and a reference beam. The path for the reference beam contains a variable attenuating element (a continuous density wedge that can be repositioned), so that the intensity of the reference beam can be matched to that of the sample beam. The wedge is calibrated in density units. Such instruments are relatively independent of fluctuations in the lamp current, but do depend on the constancy of the gray wedge in the reference beam path and the precision with which it is adjusted. In a simple design, which has a restricted measuring range and limited precision (but is still in use), the eye serves as a nulling instrument; the luminances in the two beam paths are matched.

Recording densitometers directly record the density curves. By storing a large number of density values, modern instruments also allow computer calculation and printing of the parameters of the characteristic curve.

6.1.4. Sensitivity and Evaluation

A properly exposed photograph is the central concern of sensitometry. In practice, the mean luminance of an object is determined with an exposure meter; i.e., an indicating instrument with a photoelectric detector. The exposure meter must be calibrated so as to ensure a correct exposure – within the exposure latitude – for any type of film, given an average object luminance ratio, provided the camera (aperture and exposure time) is set to the indicated "exposure" value. The parameter "light sensitivity" must correspond to the meter reading [363], [364]. Modern cameras generally have built-in exposure meters.

According to DIN 4512 (ISO 5800, ISO 2240, ISO, ANSI PH 2) the light sensitivity (DIN 12 speed) is the quantity of exposure to which a photographic emulsion must be subjected in order to form an image. From the sensitometric standpoint, it is a measure of the location of the characteristic curve relative to the exposure axis. The numerical value is the exposure that results in a stated optical density. The smaller this exposure value, the higher the sensitivity of the material; accordingly, the sensitivity number (speed) is inversely proportional to the exposure H. The German standard employs a logarithmic scale defined by the formula

$$\mathrm{DIN} = 10 \cdot \log \frac{H_0}{H_\mathrm{R}}$$

The constant H_0 is given, and H_R is determined from the characteristic curve (see below). A difference of 1 in the speed, for example between 17 DIN and 18 DIN, represents a sensitivity change by a factor of $10^{0.1} = 1.26$; a DIN number 3 higher corresponds to double the sensitivity.

The international ISO/ASA standard is arithmetic:

$$\mathrm{ISO/ASA} = \frac{1 \cdot H_0}{1.26\, H_\mathrm{R}}$$

ISO/ASA speeds are converted to DIN speeds by the relation

$$\mathrm{DIN} = 1 + 10 \cdot \log\,(\mathrm{ISO})$$

Manufacturers have recently been citing both speeds together, e.g., ISO 100/21°. A comparison of the two sensitivity scales follows:

DIN	6	7	8	9	10	11	12	13	14
ISO	3	4	5	6	8	10	12	16	20
DIN	15	16	17	18	19	20	21	22	23
ISO	25	32	40	50	63	80	100	125	160
DIN	24	25	26	27	28	29	30	31	32
ISO	200	250	320	400	500	630	800	1000	1250
DIN	33	34	35	36					
ISO	1600	2000	2500	3200					

Establishing the speed in accordance with the standard involves using precisely specified conditions of exposure, development, and evaluation. The material is exposed in the sensitometer in daylight (color temperature 5500 K) or with tungsten light (3400 or 3200 K), depending on the intended use. The radiation incident on the emulsion is adjusted for the spectral transmittance of a representative camera objective. Matching of the incident radiation to the prescribed spectral distribution is performed with liquid or glass filters [365].

Figure 64. Method for determining speed of B & W films

B & W negative films used to be developed in a solution whose composition was laid down in ISO 6 DIS 1989 (DIN 4512/1) [366]. The development time was chosen to give quite a definite form of characteristic curve such that the difference between two specified density values (on the vertical axis) was $\Delta D = 0.8$. (The densities were 0.1 and 0.9 above base plus fog.) This difference corresponded to an exposure difference of 1.3 log units (20 : 1) on the horizontal axis (see Fig. 64). For such a characteristic curve, the sensitivity point log H_m is given by the abscissa at the density of 0.1 above base plus fog. The sensitivity is then $S = 0.8/H_m$, where H_m is in lux · s. This standard, based on a special developer, is now being reworked into ISO 6 DIS 1989. Presumably the above definitions will remain in use; the manufacturer can select any process (developer), but must then include statement such as, "Material PAN X has a speed of ISO 100/21 ° for developer X at 20 °C and 4 min development time."

Color negative films must be exposed as described above and processed in accordance with the manufacturer's instructions. The printing density is measured as set forth in ANSI PH 2.27-1981 [366], [367]. No definite gradation value is specified. Since three density curves exist, there are three sensitivity points, each of which refers to a color density of 0.15 above base plus fog (Fig. 65). The sensitivity is calculated from the exposure value of the green-sensitive layer H_G and that of the less sensitive of the other two layers; i.e., the slowest layer:

$$H_m = \sqrt{H_G \cdot H_{sl}}$$

The ISO (ASA) speed is then given as

$$s = \sqrt{2}/H_m$$

Figure 65. Method for determining speed of color negative films (filters: Status M)

Color Reversal Films. A completely different criterion is used in determining the sensitivity of color reversal films. After an exposure specified in the standard and processing in accordance with the manufacturer's instructions, the visual density is measured as provided in ANSI PH 2.21 [368] or ISO 2240 (DIN 4512/4) [366]. The corresponding sensitivity point H_m on the exposure axis is found as described in ISO 2240 (DIN 4512/4) [366], [368] (see Fig. 66). The

procedure involves taking the geometric mean of H_T, the exposure for a density of 0.2 above base plus fog, and H_S, the exposure corresponding to the point where the tangent from the density point 0.2 above base plus fog intersects the characteristic curve. If the second of these points has an optical density > 2.0, the sensitivity point exposure H_m is calculated as follows:

$$H_m = (H_S \times H_T)^{1/2}$$

The speed (ASA) is then calculated as $S = 10/H_m$.

Figure 66. Method for determining speed of color reversal films (filter: visual)

The method based on an average object luminance ratio does not function for scenes having deviant luminance ratios. It is therefore recommended to give about one more stop of exposure when using reversal films during cloudy weather, that is, when the scene luminance ratio is reduced (bad-weather correction).

Measurement of Spectral Sensitivity. Photographic emulsion sensitivity depends on wavelength. The spectral sensitivity is the reciprocal of the radiant energy in a narrow range of wavelengths that produces a stated optical density.

The instrument used for measuring the spectral sensitivity is called a *spectrosensitometer*. It includes a monochromator and a device for the well-defined stepwise variation and measurement of the radiant energy per wavelength range. Another method, simpler but also less accurate, is to use a prism or grating spectrograph with a gray wedge inserted between the slit and the specimen. The sensitivity of the emulsion governs the density versus wavelength profile obtained after development (Fig. 67), which can be evaluated with a densitometer. To allow a quantitative comparison of the results, the energy distribution of the lamp spectrum must be taken into account and the measured spectral sensitivity must be converted to a "constant-energy spectrum."

Figure 67. Spectral sensitivity of different sensitized materials
A) No optical sensitization: blue sensitive; B) Orthochromatic: blue and green sensitive; C) Panchromatic: blue, green, and red sensitive; D) Blue and infrared sensitive

Pure silver halide emulsions have no sensitivity except in the ultraviolet and blue regions (Fig. 67 A). The region of sensitivity expands into the long-wavelength infrared only after spectral sensitization with dyes. The following terminology has come into use for describing the spectral sensitivity of emulsions. *Orthochromatic*: additional sensitivity in the green to about 560 nm (Fig. 67 B). *Panchromatic*: intrinsic sensitivity plus additional sensitivity in the green and red to ca. 680 nm (Fig. 67 C).

The purpose of *sensitizing B & W films* for pictorial use is that the brightness values of surface colors occurring in nature should be reproduced as they are seen by the eye. Compromises are necessary for the sake of greater light sensitivity. The use of a yellow filter reduces the blue component of the spectral sensitivity and often results in a better visual impression.

In *color photography*, each emulsion layer is sensitized for a certain color. For example, the yellow layer is sensitized for blue light; the blue component of the light is subsequently removed by a yellow filter for the panchromatically sensitized emulsions lying beneath. The sensitivities of the emulsions in a color film are matched to the spectral energy distribution of the light illuminating the scene. Daylight contains more blue and less red than the light from an incandescent tungsten lamp. Accordingly, in daylight reversal film the blue layer is less sensitive than the green and the red layer is more sensitive than in films with tungsten light. Departures from the specified light color, such as daylight exposures with the sun low in the sky, may produce a marked color imbalance in the image, as can the use of photographic objectives with "atypical" spectral transmittances. Reducing the short- and long-wavelength limits of the spectral sensitivity makes it possible to diminish the effects on the photograph due to differences in the type of light (universal sensitization). Similarly, the use of a filter on the camera can render a film sensitized for one type of light (e.g., tungsten) usable with another (e.g., daylight).

6.1.5. Sensitometry of Printing

Negative films represent an intermediate stage in the creation of an image. They are printed onto a suitable positive or print material (a positive film or paper). The brightness distribution of an original object is reproduced (tonal reproduction) in the best possible way if the image contrasts match the luminance levels in the scene, that is, if the print has a gradation value of 1 relative to the original. Hence the corresponding portions of the characteristic curves for the negative and the positive should be related as follows (Goldberg condition):

$$\left[\frac{\mathrm{d}D}{\mathrm{d}\log H}\right]_{\mathrm{neg}} \cdot \left[\frac{\mathrm{d}D}{\mathrm{d}\log H}\right]_{\mathrm{pos}} = 1$$

The Goldberg condition [34], [37] can be exactly satisfied only in the straight-line portion of the characteristic curve. Exact calculations should, moreover, take into account the effect of flare light in the camera and printing apparatus. The result of a printing operation (printing curve) can be plotted by using the characteristic curves of the negative and positive materials [369]. To meet the Goldberg condition, the flat gradation of negative films must be offset by a markedly higher gradation of the print material. Hence papers must have gradation values > 1, which means that the maximum exposure latitude (called printing latitude) is limited. For positive film, the latitude is ca. 3.0 log units. Papers must be exposed so precisely that detail is still present in the highlights and shadows even when the nonlinear parts of the characteristic curve are included. B & W papers are therefore available with a range of gradations or "hardnesses" so that the range of negative density differences can be accommodated. The light sensitivity of the positive material is not critical unless economic factors such as printing time must be considered.

The measurement of speed in *B & W materials* is governed by an ISO/ANSI standard [370]; (see Fig. 68); H_{m} is the exposure that produces a net density of 0.6. The speed is then calculated as $S = 1000/H_{\mathrm{m}}$. The printing range is given by $R = \log H_{\mathrm{S}} - \log H_{\mathrm{T}}$, where H_{S} is the exposure at 90 % of maximum net density and H_{T} is the exposure at 0.04 above base and fog density. At present no standard exists for *color papers*.

Figure 68. Determination of ISO speed and range of printing for black and white continuous-tone papers, Filter: visual
a) Speed point; b) Average gradient; c) Base plus fog density

In printing from color negatives, the dyes simultaneously act as filters. For example, the blue component in the printing light is modulated by the yellow color density of the negative before

exposing the blue-sensitive emulsion in the positive material. Aside from the secondary color densities of the individual layers, a given dye layer in the negative prints to the same dye layer in the positive. Under these idealized conditions, the Goldberg condition holds separately for the yellow, magenta, and cyan layers. If a pair of layers fails to satisfy the condition, a color error occurs in the print. For example, if the magenta in the negative is too steep relative to the other layers, the positive will show green highlights and magenta shadows.

Theoretically, a gradation departure in one layer of the negative material could be compensated by a departure in the opposite sense in the corresponding positive layer. In the example just described, a flat magenta in the print material would offset the error. In practice, the approach is not used. Negative and positive materials are separately made "equivalent neutral", so that products from different manufacturers can be used interchangeably.

Figure 69. Effect of subtractive filter on print material

An important advantage in color copying is that color imbalances in the positive and the negative can be corrected by adjusting the color of the printing light. In the subtractive process, this is performed by inserting appropriately colored printing filters. Figure 69 shows how a magenta cast in the positive is remedied by a magenta filter, which reduces the exposure of the excessively fast green-sensitive emulsion. The use of the filter shifts the magenta curve to the right. An imbalance in the negative due to sensitivity mismatches between the emulsions cannot, however, be exactly filtered out in the fog region, so that a color tilt can occur in the dark portions of the image. Figure 70 illustrates the case of a cyan emulsion (a) that is less sensitive than the magenta and yellow emulsions (b). A cyan filter shifts curve (a) upward by the filter density (d) to c. Only the straight-line portion can be brought to coincide with curve (b). The fog plus base part of the curve, on the other hand, takes on a cast of the filter color.

Figure 70. Unbalanced color negative film
a) Cyan emulsion; b) Magenta and yellow emulsions; c) Fog plus base part; d) Filter density

Because it is fairly easy to compensate for color imbalances in printing, color negative films need not be strictly balanced for the color temperature of the light on the scene. For this reason, most color negative films now on the market are daylight types, which can be used under any lighting conditions that occur in practice, given proper exposure. In motion-picture work, however, standards are higher and filters must be used on the camera under unusual lighting conditions. The use of camera and printing filters can remedy only overall casts. Mixed light sources, for example, sunlight and tungsten light, must therefore be avoided. Up to this point, the effect of minor color densities of the dye layers on the sensitometric result has not been taken into account. In the two-step negative – positive process, and especially in multistep processes, secondary absorptions of the negative dyes lead to inadequate dye formation or dye formation in the wrong layer in the positive material. Because the positive will show further reproduction errors, the multistep process will result in more hue shifts and chroma losses than the reversal process. Negative films do, however, offer the possibility of improving color reproduc-

tion through the use of "color masks." These are emulsion layers in the color of the minor color density. Their sensitometric action consists in compensating for the image produced in the "minor" color by an opposite (inverted) gradation, thus producing a uniform fog density. This fog in the minor color does not appear in the print, so that the chroma of the major color is improved. Modern color negative films therefore contain masking dyes incorporated in the emulsion layers (see Section 5.2.2.3).

The high yellow and magenta fog level in color negative films, which largely determines the position of the printing density curves (Fig. 65), is accounted for by the incorporated masking dyes.

6.1.6. Sensitometry of Interimage Effects
(see also Section 2.3.4)

In addition to the use of masks to minimize the minor densities (see Section 6.1.5) of the dyes, color reproduction can also be improved through interimage effects. Figure 71 illustrates the principle. This effect can be strongly promoted by DIR compounds. Such compounds flatten the gradation given a neutral exposure: roughly equal amounts of DIR couplers are released in all the emulsion layers on development, thus inhibiting the yellow, magenta, and cyan layers equally. The film remains neutral. If, on the other hand, the film is exposed in red light, only small amounts of DIR couplers appear in the yellow and magenta layers, while the quantity liberated in the cyan layers grows larger and larger as the exposure increases, so that these compounds can diffuse into adjacent layers. This means that the cyan layers are not as strongly inhibited as the other layers. The gradation becomes steeper, and in this way the color reproduction is improved. IN 1987 there is no ISO standard on the sensitometry of interimage effects [34–36]. The gamma is referred to a value of 1 for neutral exposure; if the selective red exposure gives 40 % interimage effects in the cyan, then $\gamma = 1.4$. Additive neutral exposure (red+green+blue) generates less cyan dye than the same amount of red exposure only. Thus the layers influence one another (interlayer effects). If, for example, the film is exposed with green light (wedge) and uniformly with red light, the action of the DIR couplers suppresses the cyan densities with increasing green exposure. This corresponds to masking and improves the purity of the colors; (see Fig. 72). The cyan density has a negative gradient: $\gamma = -0.2$. The same procedure can be followed for any other combination of layers, yielding an interimage-effect matrix as shown below. In this example it was assumed that all the layers (yellow, magenta, and cyan) have 40 % interimage effect, 20 % of which is due to each of the other layers.

$$M = \begin{array}{c} \text{(yellow)} \quad \text{(magenta)} \quad \text{(cyan)} \\ \begin{pmatrix} 1.4 & -0.2 & -0.2 \\ -0.2 & 1.4 & -0.2 \\ -0.2 & -0.2 & 1.4 \end{pmatrix} \end{array} \begin{array}{l} \\ \text{(blue)} \quad \text{(blue)} \\ \text{(green)} \quad \text{(green)} \\ \text{(red)} \quad \text{(red)} \end{array}$$

6.2. Tonal Reproduction and Image Structure (see also Section 2.4.1) [2], [4],[19], [38]

6.2.1. Tonal Reproduction

The task of the photographic emulsion is to record and store optical information. The information may comprise a portrait, a landscape, or a microfilm of a technical drawing. In any case, the intensity pattern generated in the plane of the film must be transferred without distortion. The emulsion can achieve this only to a limited extent because it is not a structureless image storage medium, but consists of a gelatin matrix in which light-sensitive silver halide crystals reside in a statistical distribution. The quality of image transfer is essentially described by the characteristic curves, the granularity, and the sharpness of the material employed.

Characteristic Curve. The characteristic curve (see also Section 6.1.2) is the most important graph used to assess the emulsion as an information medium. It shows how the optical density D (-log τ) resulting after development depends on the exposure H. In accordance with the scattering power of the developed emulsion, two kinds of transparency are distinguished: the diffuse transparency $\tau *$ and the transparency τ'' measured in parallel light (Callier coefficient $C = D''/D *$) [374].

Figure 71. Interimage effect, red and neutral exposure
Y=Yellow layer; M=Magenta layer; C=Cyan layer

Figure 72. Interimage effect, green exposure and constant red exposure
Y=Yellow layer; M=Magenta layer; C=Cyan layer

The exposure H is usually plotted logarithmically on the horizontal axis (see Fig. 59). The shape of the characteristic curve strongly depends on the emulsion, its laydown on the support, and the development.

The increase in density with exposure generally results from an increasing number of developed grains per unit area. According to a simple but frequently applicable model (due to NUTTING)

$$D = 0.434 \cdot n_f \cdot \frac{a}{f}$$

where n_f is a number of grains per area f and a is the mean effective grain cross section [19], [375].

At the toe of the characteristic curve (Fig. 59), that is, near H_0, a limited number of large, sensitive grains are exposed. On the linear portion of the curve, the number of developable medium-sized and small grains becomes greater and greater. The onset of saturation, finally, indicates that greater exposures will not make any more grains developable. The fact that a certain exposure renders a certain fraction of the silver halide grains in an emulsion developable implies that each individual grain must have its own critical threshold number of photons, beyond which it becomes developable. This minimum number of photons that must be absorbed may depend on grain size or may vary within a single grain-size class (sensitivity distribution).

How many photons are actually absorbed by the individual grain at a given exposure partly depends on the grain size, which is generally not uniform in an emulsion (grain-size distribution), and partly on the location of the grain in the emulsion layer (depth distribution of exposure). Finally, the statistical distribution of incident photons has the consequence that grains of equal size and depth have different numbers of photons available for absorption (Poisson distribution of absorbed photons).

If these distribution functions are known, the number of developed grains can be calculated as a function of the exposure, if some simplifying assumptions are made. The characteristic

curve can be determined by Nutting's method if it is further taken into account that the density contributions of the developed grains depend on their size.

Detailed treatments of the theory of optical density are found in [2], [4], [19], [32], [34]. For the practical meaning of the characteristic curve and, in particular, the extension of this concept to color photography, see Section 6.1. The gradation in the finished photograph should be chosen so as to produce the most natural impression possible of the object imaged.

6.2.2. Granularity

If the developed emulsion is examined after uniform areal exposure, the structure appears homogeneous at first but becomes irregular as the enlargement is increased. This impression, which gives the examiner an impression of reduced quality, is called *graininess*. *Granularity*, in contrast, refers to the same phenomenon in the form of objectively measured local density fluctuations, such as can be recorded for the same specimen by a microphotometer with a sufficiently small measuring aperture. Both these terms relate to an important property of the photographic system as an information-transfer medium. This property results from the sensitivity distribution of the silver halide grains and the random arrangement and sizes of the developed silver grains [4], [19], [34], [38]. The grains themselves are too small to be detected at common magnifications, but the number of grains per unit volume fluctuates for the reasons stated above.

Graininess. Graininess comparisons between photographic materials are generally carried out by exposing a series of distinct, sufficiently large ($> 1\ \mathrm{cm}^2$) areas of each specimen, and then developing. On the test strips, negatives of equal density are then selected, enlarged by a factor of 12, examined, and compared.

Another common procedure is based on increasing the enlargement until the graininess becomes disturbing. The enlargement is then reduced until it is just impossible to perceive the random structure. The reciprocal of this enlargement limit is a measure of the graininess [376].

An essential condition for the success of such test methods is consistent processing of all materials; special care should be taken that all test strips are developed to the same gradation and that comparisons are performed only in regions of equal optical density, since graininess and its detectability depend on development and density.

The drawbacks of such methods are the rather laborious procedure of specimen preparation and the lack of objectivity in the numerical values or rankings obtained.

Granularity. Granularity comparisons between photographic materials can be done with a variety of objective methods. These techniques and the quantities obtained are quite similar to noise analysis techniques in electronics, for granularity is the counterpart of noise in electronic transmission channels. The starting point for all methods is the transformation of grain noise into electrical noise by photoelectric scanning in a microphotometer (Fig. 73). The scanned track x may be circular or straight, since granularity in photographic emulsions is isotropic. The position coordinate x is linked to the time coordinate t of the electrical signal through the scanning rate v [371].

The most common way of plotting granularity is to record the rms value σ (see below) as a function of optical density D at a constant aperture area (Fig. 74). The curve is derived from the density variations $D(x)$ recorded when scanning the longest possible track X:

$$\sigma_{D,f} = \left[\frac{1}{X} \int_0^X \left(D(x) - \bar{D} \right)^2 \mathrm{d}x \right]^{\frac{1}{2}}$$

where $\bar{D}$ is the mean density, defined as

$$\bar{D} = \frac{1}{X} \int_0^X D(x)\, \mathrm{d}x$$

The rms value is defined similarly to the effective value of an AC voltage, so that in the extended sense $(\mathrm{rms})^2$ can be regarded as a measure of the power of the grain noise. The dependence of the rms value on the selected aperture area f is represented by the subscript f. The two equations above are mathematically exact only as $X \to \infty$. In practice, the rms value is also determined as

Figure 73. Optical system of a microdensitometer including electronic equipment
a) Lamp; b) Illuminating condenser; c) Field slit; d) Image of field slit or aperture; e) Illuminating microscope; f) Sample holder (rotating or translating) movable stage; g) Collector microscope; h) Scanning slit or aperture; i) Diffuser; j) Photomultiplier; k) High voltage power supply; l) Amplifier (plus log- converter and ADC); m) Computer (stage motion control and data analysis); n) Plotter, printer

$$\sigma_{D,f} = \left[\frac{1}{n}\sum_{i=1}^{n}(D_i - D)^2\right]^{\frac{1}{2}},$$

$$\bar{D} = \frac{1}{n}\sum_{i=1}^{n} D_i, n \geq 1000$$

Many formulas exist for calculating the granularity from the fundamental elements of the emulsion [377]. The simplest model leads to the Siedentopf formula [372]:

$$\sigma^2_{D,f} = 0.434 \cdot \bar{D} \cdot \frac{a}{f}$$

This equation holds only if the area f of the measuring aperture is much larger than the mean effective grain cross section a and if the grains have a statistically independent distribution. These conditions are fairly well satisfied for B & W films and apertures larger than 10 µm in diameter [373], [378], so that the Selwyn granularity G_D, defined as

$$G_D = \sigma_{D,f} \cdot \sqrt{f}$$

is constant here too provided the density D is constant [379]. The fact that G_D is independent of aperture was the reason that the Selwyn granularity was preferred as an emulsion parameter for a long time. But modern color materials are far from satisfying this condition, and so the rms values are now preferred.

Unfortunately the measuring apertures used in reported studies have different diameters (12 – 50 µm); hence, the rms values obtained cannot be compared easily. The diameter should be selected such that the microphotometer – aperture system simulates the viewing conditions for visual assessment as well as the optical properties of the human eye (48 µm diameter and 12 x enlargement). The rms value and the graininess rating could then be correlated.

Figure 74. RMS-values as a function of density for
a) Color reversal film, 100 ASA; b) Color negative film, 100 ASA
Filter = visual

Frequency Analysis. The most complete and objective information on granularity comes from a frequency analysis of the grain noise. One way of performing such an analysis is to proceed as in the rms measurement but to feed the electronic noise from the microphotometer output to a filter having the narrowest possible passband $\Delta\nu*$ about the center frequency ν. By varying $\nu*$ while keeping the bandwidth $\Delta\nu*$ constant, a noise value, rms($\nu*$, $\Delta\nu*$), is obtained for each frequency band $\nu*$, $\Delta\nu*$. This noise value depends on the mean density $\bar{D}$ of the specimen and the area and shape of the measuring aperture. Since the electrical frequency $\nu*$ is generally equal to the product of scanning rate v and spatial frequency ν, the noise power per unit spatial frequency $\sigma^2{}_{D,f}\,(\nu, \Delta\nu)$ can be plotted versus the spatial frequency ν. The resulting curve is called the power-density spectrum $N_{D,a}\,(\nu)$ of the grain noise. The mathematically exact definition of this spectrum is

$$N_{D,f}\,(\nu) = \lim_{\Delta\nu\to 0} \frac{\sigma^2_{D,f}\,(\nu,\Delta\nu)}{\Delta\nu}$$

Because the granularity contributions of the individual spatial-frequency intervals simply add to give the total granularity, the following applies:

$$\sigma^2_{D,f} = \int_0^\infty N_{D,f}\,(\nu)\,\mathrm{d}\nu$$

The power-density spectrum $N_{D,f}\,(\nu)$ depends on the mean density $\bar{D}$ and on the area and shape of the measuring aperture. If constraints due to the microphotometer optics are neglected, then

$$N_{D,f}\,(\nu) = N_D\,(\nu) \cdot \left|M_f\,(\nu_x, \nu_y)\right|^2$$

Here $M_f\,(\nu_x, \nu_y)$ is the modulation transfer function associated with the measuring aperture f. In general, it depends on the aperture dimensions and its orientation is relative to the scanning direction (see Section 6.2.3). $N_D\,(\nu)$ is the true power-density spectrum (Wiener spectrum) of the photographic emulsion, which can be derived from the above equation with little mathematical difficulty, if a very long, narrow slit is used as the aperture and the scanning direction is perpendicular to the long axis of the slit.

Figure 75. Power spectral density of a B & W film
a) Exposure by light; b) Exposure by X-rays

In *B & W films* exposed with visible light, all spatial frequencies make roughly equal contributions to the Wiener spectrum (Fig. 75, curve a). For this "white-noise" case, $N_D\,(\nu) = N_D\,(0)$, so that the Selwyn granularity is $G^2{}_D = N_D\,(0)$.

For exposure with X-rays, grain agglomerates are formed because an X-ray quantum renders a large number of grains developable. Corresponding to this frequently-encountered coarse structure in position space are low spatial frequencies in frequency space, so that the Wiener spectrum shows a marked exaggeration at low spatial frequencies (Fig. 75, curve b).

Detailed mathematical analyses (Fourier transforms, autocorrelation, etc.) and methods of measuring the Wiener spectrum are discussed in [19], [34], [38], [378].

Figure 76. Improvement of granularity by DIR- couplers
a) Without DIR- couplers; b) With DIR- couplers

The techniques just described for measuring graininess and granularity in B & W materials can also be applied to *color materials.* Selecting appropriate color filters makes it possible to study the granularity and the Wiener spectrum of individual emulsion layers. The graininess rating and the measured granularity correlate well if the contributions to the total noise power are weighted with the sensitivity characteristic of the eye: magenta 60 %, cyan 30 %, and yellow 10 %. For color reversal materials, a filter is employed that combines with the spectral sensitivity of the photomultiplier to reproduce the sensitivity of the eye. Both interpretation and theory relating to the measured color granularity are far more complicated than in the case of B & W granularity [380], because the dye clouds are transparent, unlike the developed silver grains, and because the relationships between the silver halide grain and the dye cloud are indirect (with the diffusible developer oxidation product as intermediate stage). In addition, the three color-generating layers may interact.

The Nutting and Siedentopf formulas imply that the granularity decreases as the number of silver grains per unit area increases. Since 1972, DIR couplers have been used to improve (i.e., decrease) the granularity [381] (Fig. 76; see also Section 5.2.2.3). During color development, inhibitors are released and prevent the complete reduction of the silver halide grain. The result is that smaller dye clouds are formed. In order to achieve the same density, more grains are needed; this implies a lower granularity than in a film without DIR couplers.

6.2.3. Sharpness

If the developed emulsion is examined after an exposure containing small details, a sufficient enlargement will reveal that the boundaries between image regions differing in luminescence have become inexact and that details in the original of less than some definite size are no longer discernible in the image. If defects in image recording (e.g., blurring or incorrect focusing) are not present, the subjective impression gained from such a visual examination characterizes the sharpness of the developed emulsion. Avoiding errors in the assessment depends strongly on separating the effects of sharpness and granularity on the quality of image transfer, since grain noise also makes it impossible to distinguish details when the signal – noise ratio is not sufficiently high. The sharpness is the third important transfer property of photographic materials. It results from the behavior of the emulsion elements (light scattering) and from processes occurring in development (color formation, edge effects) [2], [4], [19], [34], [38]; see also Section 2.4.1.

"Visual sharpness" comparisons between photographic materials are carried out by essentially the same methods known from grain investigations, except that large-area exposure is replaced by suitable test objects.

An objective, numerical measure of sharpness, which is relatively easy to measure and correlates fairly well with the visual assessment, is obtained from the density curve of an exposed edge. After exposure and development, the edge pattern in the material is placed in the beam of a mirophotometer and scanned. In order to suppress the granularity, an aperture in the form of a slit, narrow in the x direction and as long as possible in the direction parallel to the edge, is used. The density curve $D(x)$ is illustrated in Figure 77. The density begins to increase even before x_0, that is, in the geometrical shadow re-

gion of the edge, but does not reach its maximum value until considerably beyond x_0. The edge is reproduced in smeared-out form. The reason for this loss of sharpness is light scattering, for the undeveloped emulsion can be regarded, from the optical standpoint, as a plane-parallel layer of a medium containing haze. The scattering inhomogeneities are the grains, whose refractive index (ca. 2.2) differs markedly from that of the surrounding gelatin matrix (1.5). During exposure, an illuminance distribution occurs at the emulsion surface (external exposure; see Fig. 77). Inside the layer, this distribution is modified by scattering, absorption, and reflection (internal exposure). As a result of scattering, light diffuses into the geometrical shadow of the edge (light spread), degrading the sharpness. Light quanta can also reach the back of the film base, where they are reflected, again reducing the sharpness (halation). In commercial materials, however, this effect is largely blocked by an antihalation layer.

Figure 77. Light scattering in a photographic emulsion
a) Photons (exposure); b) Absorbed photons; c) Re-emitted photons; d) Transmitted photons; e) Knife edge exposure; f) Density distribution after development

The numerical sharpness value is derived from the measured density profile. The position coordinate is subdivided into small, equal intervals Δx_i, and the mean square slope $(\bar{D})^2$ in the edge is calculated with the formula

$$(\bar{D})^2 = \frac{1}{n}\sum_{i=1}^{n}(\Delta D_i/\Delta X_i)^2$$

If the density change ΔD in a comparison is not constant, the acutance, AC defined as

$$AC = \frac{(\bar{D})^2}{\Delta D}$$

correlates rather well with the visual assessment [382].

Modulation Transfer Function. The introduction of information theory and its associated frequency-domain representation into optics [19], [38] has made the modulation transfer function (MTF) the most important descriptor of the sharpness of photographic materials. This function $M(\nu)$ states quite generally how the modulation transfer of a locally sinusoidal illuminance distribution $E\left(\vec{r}\right)$ having spatial frequency $\vec{\nu}$ (sine-wave pattern) is changed in the imaging system. In principal, any optical system – a microphotometer, a circular aperture, or a measuring slit – has an MTF [2], [19], [34], [38]. In order to measure the MTF of a photographic material, sine-wave patterns having various spatial frequencies are exposed onto the material. The spatial distribution of the external illuminance is then

$$E(x) = E_0\left[1 + m(\nu)\cdot\sin(2\pi\nu x)\right]$$

where E_0 is the mean intensity and $m(\nu)$ is the input modulation. Light scattering in the emulsion causes the modulation of the illuminance distribution to change as a function of the spatial frequency. The higher the spatial frequency, the smaller the amplitude of the internal illuminance $E(x)$:

$$E(x) = E_0\left[1 + m'(\nu)\cdot\sin(2\pi\nu x)\right]$$

The ratio of the modulations of the internal and external exposures at a given spatial frequency ν gives the modulation transfer factor $M(\nu)$:

$$M(\nu) = \frac{m'(\nu)}{m(\nu)}$$

The functional relation between $M(\nu)$ and the spatial frequency is the MTF. The procedure

is illustrated in Figure 78 [383]. Any spatial exposure distribution $H\ \vec{\nu} = E\left(\vec{\nu}\right) \cdot t$ can be uniquely expanded in two-dimensional sine and cosine functions varying in amplitude and phase (Fourier transform). Thus, if the MTF is known, the photographic image of an object can be calculated in the following way: the MTF is multiplied by the Fourier transform (spatial-frequency spectrum) of the external exposure, and then the inverse Fourier transform is applied to the product (the spatial-frequency spectrum of the internal exposure). The result is the spatial distribution of the internal exposure. Conversely, any object can be used for measuring the MTF if the spatial-frequency spectra of the external and internal exposure are known. Thus, in addition to the classical method based on a sine-wave pattern [384], [385] (where the transfer of discrete frequencies is measured) other methods exist. These alternative methods employ square-wave patterns [386], knife-edges [387], [388], and noise patterns [389] of selected bandwidth. The last method is quite similar to the way the frequency response of an electronic transmission channel is measured.

Figure 78. Modulation transfer function, principle
Unit of spatial frequency is line pairs per millimeter (lp/mm)

All the methods are similar in that the internal exposure is calculated from the characteristic curve derived from the microphotometric measurement of the transparency or density distribution in the developed image. In fact, the density distribution is the crucial output signal. This operation is necessary because, as shown by the characteristic curve, the relationship between the internal exposure and the developed optical density is nonlinear. It follows that, if a sinusoidal exposure distribution is transferred to the corresponding optical density, the sinusoidal form generally is not retained; the output contains distortions analogous to overtones in electronics. This effect can be suppressed by making the modulation of the external exposure sufficiently small. In the region under consideration, the characteristic curve is linear to a good approximation, so that the concept of the MTF still applies to the transfer from the illuminance distribution to the density distribution.

Figure 79. Schematic diagrams of adjacency effect
A) Exposure, knife edge; B) Diffusion of reaction products; C) Contrast without (dashed line) and with adjacency effect (solid line)

A completely different cause gives rise to a second nonlinearity between exposure and density. This is due to *diffusion effects in development* and therefore depends strongly on the developer composition and the agitation of the specimen while being developed. At the boundary of a uniformly exposed region, which consumes corresponding amounts of developer, fresh developer can diffuse into the edge of the region from the surrounding zone of lower exposure. In this way, the optical density inside the edge becomes higher than the density aver-

aged over the region. On the other hand, oxidation products from the region of high density can diffuse into the adjacent region, restraining the formation of density, so that regions of low density show a fringe of reduced density in front of the transition to darker regions (Fig. 79). The strength of this *adjacency* or *Eberhard effect* depends on the density difference as well as the absolute density [381], [390], [391]. It may be so pronounced that, e.g., in the region of a slit, a density is developed such that a back- calculation with the characteristic curve would show an internal exposure greater than what was actually present (see Fig. 80). This means that small details are reproduced with higher contrast. This effect is greatly intensified by DIR couplers, in modern color negative films. In general, adjacency effects work to the benefit of the perceived sharpness. These effects are also described by the MTF, which can take on values greater than unity (see Fig. 81). Where an edge is exaggerated, however, the MTF behaves similarly to the Eberhard effect; hence, to characterize the sharpness of the photographic material – which is governed by light scattering and the edge effect – it would be necessary to determine a family of MTF curves with the mean density and input modulation as parameters. When two materials are being compared, however, it is usually sufficient to measure an MTF for each at equal mean densities and not too great an input modulation, provided the two specimens are nearly equal in sensitometry [381].

Taking the constraints cited into consideration, the modulation transfer function of an entire imaging system containing the photographic emulsion can be determined (MTF system). With such an MTF system, parameters of the image sharpness can be obtained or – what is often more important – the object can be reconstructed from the existing image. The basis for the calculations is the multiplication theorem [19], [34], [38], which states that the MTF of an imaging chain equals the product of the MTFs of the links in the chain, provided all transfer the signal in a linear way. The assessment of the chain camera – film – projector – screen is given as an example. For each spatial frequency, the individual modulation transfer factors are multiplied with allowance for the enlargements between steps. To get a good correlation to the visual impression, the resulting MTF is multiplied by the MTF of the eye, again with allowance for the way the viewing conditions affect the spatial-frequency axis. The area under the overall MTF gives a measure of sharpness (CMT acutance) [392], [393].

Besides the sharpness measures obtained in a similar way [392], [393], a figure of merit based on the MTF (sharpness) and the Wiener spectrum (granularity) has been proposed. The calculations lead to good agreement with the visual impression [394].

The concepts and methods for sharpness measurement can be extended from B & W to color materials; the MTFs of the individual layers can be measured through the choice of suitable color filters. The MTFs not only represent the variation in external exposure due to light scattering and egde effect, but also include the effect of color formation on sharpness.

In color development, the light quantum absorbed in the silver halide is made detectable by means of developed density not at the point where it was absorbed, but where the developer oxidation product diffusing away from the grain reacts with the dye coupler. This process degrades the sharpness, so that the MTF of a given color layer, by the multiplication theorem, is the product of three factors: MTF(S) (= scattered light), MTF(C) (= color development), and MTF(E) (= edge effect). In the multilayer color film, the scattered-light component becomes more distinct from layer to layer (in the irradiation direction). In this way, edges and stripe structures may be edged in the color of the next lower layer.

For the same reasons as cited for granularity, the magenta MTF has the strongest influence on the visual impression of sharpness.

Monte Carlo calculations of the MTF on modern high-performance computers have become a powerful tool for optimizing complicated multilayer structures with respect to sharpness. This is important because average emulsions have grain diameters of the order of the wavelength of light, and this means that scattering takes place in the range governed by Mie scattering [394]. Mie scattering theory is particularly complicated, whereas the Monte Carlo technique allows the calculation of light scattering in structures, no matter how complex they are. Monte Carlo calculations are used to obtain

point or line spread functions and information on the sensitivty. The MTF is then derived from the line spread function by application of the Fourier transform [395–398].

Figure 81. Influence of the adjacency effect on the modulation transfer function
a) MTF without adjacency effect; b) MTF with adjacency effect; c) MTF of the chemical spread function

6.2.4. Resolving Power [19], [38], [399]

The resolving power (RP) is the reciprocal of the distance between two details (e.g., bars in line grating) when the images of these details on the photographic emulsion are just distinguishable from each other. Despite is shortcomings, the resolving power continues to be used as a measure of the transfer properties of photographic materials. this is understandable because the measurement can be done without costly apparatus.

The resolving power is determined by exposing line gratings with increasing spatial frequency onto the emulsion, often in varying intensity (Fig. 82). Accordingly, to MTF the contrast between light and dark bars must become smaller and smaller as the spatial frequency increases. In addition to this light-scattering effect, the eye experiences more and more interference due to graininess in the microscopic examination, so that ultimately the density variation due to the exposure "drowns" in the graininess.

Figure 82. Line gratings for evaluating the resolving power

It follows that the resolving power depends on both the MTF and the granularity. In a given photographic material, the same RP can result from a good MTF and high graininess or from a poor MTF and low graininess. In the same way, two emulsions having equal modulation transfer functions can have completely different resolving powers. What is more, the sharpness of an image in practice is governed not just by the film, but also by the camera, whose MTF may be such that the film cannot display its full resolving power. In such cases, a high numerical RP has no predictive value and it is only important that the MTF has its maximum values in the range of spatial frequencies that the camera transfers well. But the major drawback of the resolving power is that the procedure is not objective [399].

6.3. Color Reproduction [35], [400], [401]

An important goal of color photography is to produce colors in the image as near as possible to those that the human eye saw in the object. Subjective factors, however, play a major role in the optimization of color reproduction (e.g., in the case of skin tone). Electromagnetic radiation

preceived as "light" or "color" is radiation incident on the retina of the human eye and having wavelengths between about 400 and 700 nm.

The retina contains three types of *stimulus centers* (cones) for color vision; these differ in spectral sensitivity. The impression of color is produced by the intensity of the three stimuli transmitted to the brain.

Figure 83. CIE tristimulus functions according to CIE Publication no. 15.1 and DIN 5033

In *colorimetry*, the vision process is simulated by metrological apparatus. The conventional spectral sensitivity distributions for the eye model are embodied in the spectral tristimulus values set forth internationally by the Commission Internationale de l'Eclairage (CIE); see also → Dyes, General Survey, Chap. 3. The radiation reflected or transmitted by an object – the product of the incident radiation $E(\lambda)$ (normally standard illuminant A for tungsten or D_{65} for daylight) and the spectral reflectance $R(\lambda)$ or transmittance $T(\lambda)$ – is integrated with the spectral tristimulus functions $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, $\bar{z}(\lambda)$ in order to obtain the CIE tristimulus values X, Y, Z where 380 and 775 nm are the lower and upper integration limits and k is a normalization factor:

$$X = k \int_{380}^{775} \bar{x}(\lambda) \cdot E(\lambda) \cdot R(\lambda)\, \mathrm{d}\lambda$$

$$Y = k \int_{380}^{775} \bar{y}(\lambda) \cdot E(\lambda) \cdot R(\lambda)\, \mathrm{d}\lambda$$

$$Z = k \int_{380}^{775} \bar{z}(\lambda) \cdot E(\lambda) \cdot R(\lambda)\, \mathrm{d}\lambda$$

The three tristimulus values provide a measure of the three stimuli sent to the brain (Fig. 83). The set of all color locations (X, Y, Z) forms a three-dimensional color space (CIE – XYZ system). This color space is not visually equispaced; an equal geometrical distance between two color locations almost never corresponds to an equal difference as visually perceived.

The CIE – XYZ system can be remapped into a visually equispaced system according to several international standard methods. After the remapping, an equal (Euclidean) distance between any two color locations corresponds to an approximately equal visually perceived difference. The CIE – $La*b*$ 1976 formula (CIE Publication no. 15.2) is given as an example in what follows:

$$\text{Luminance}\, L = 116 \cdot \left(\frac{Y}{Y_0}\right)^{1/3} - 16$$

Red – green portion $a*$

$$a^* = 500 \cdot \left[\left(\frac{X}{X_o}\right)^{1/3} - \left(\frac{Y}{Y_0}\right)^{1/3}\right]$$

Yellow – blue portion $b*$

$$b^* = 200 \cdot \left[\left(\frac{Y}{Y_o}\right)^{1/3} - \left(\frac{Z}{Z_0}\right)^{1/3}\right]$$

where X, Y, Z are the tristimulus values for the sample and X_o, Y_o, Z_o are the tristimulus values for the reference illuminant.

Color differences according to the CIE – $La*b*$ formula (CIE Publication no. 15.2, DIN 6174) are as follows: Given two specimens with L_1, a_1*, b_1* and L_2, a_2*, b_2*, then the CIE – $La*b*$ color difference is

$$\Delta E = \left[(L_2 - L_1)^2 + (a_2^* - a_1^*)^2 + (b_2^* - b_1^*)^2\right]^{1/2}$$

This can be broken up into lightness, chroma, and hue components, whose squares sum to the square of ΔE

$$\Delta E^2 = \Delta L^2 + \Delta C^2 + \Delta H^2$$

The luminance difference is

$$L = L_2 - L_1$$

The chroma difference is

$$\Delta C = \left(a_2^{*2} + b_2^{*2}\right)^{1/2} - \left(a_1^{*2} + b_1^{*2}\right)^{1/2}$$

The hue difference is

$$\Delta H = \left(\Delta E^2 - \Delta L^2 - \Delta C^2\right)^{1/2}$$

The three-dimensional character of the color space accordingly dictates three criteria for the characterization of color differences: luminance, chroma, and hue.

In the color plane (L = const), color differences are represented as shown in Figure 84.

Figure 84. CIE-$La*b*$ color plane for L = const

Colorimetry can also be used to represent the color reproduction of photographic materials in the CIE – $La*b*$ color space. By way of example, Figure 85 shows the color rendition in a color negative – positive system. The measurements were performed on prints made on Agfa Type 8 color paper from two color negative films: the older XRi-100 (film 1) and the new XRG-100 (film 2). The object photographed was the Agfa color chart with its six colors (blue, green, red, yellow, magenta, cyan). Correct conditions were maintained as to exposure and filtration during both exposure and printing (see Section 6.1). For ease of visualization, the color locations are joined by lines to form a color hexagon in the color plane (color gamut). The lightnesses in the original and the prints are not considered here. Modern color films thus yield better results as to chroma and hue, partly because of strong and optimized interimage effects (see also Section 6.1.6).

Figure 85. Color planes of two films
B = blue; C = cyan; G = green; M = magenta; R = red; Y = yellow

6.4. Stability of Images [34]

6.4.1. Introduction

The discovery of photography dates back to approxi mately 1826. In historical terms, this is a short span of time. Nonetheless, photographic images from this period are of great documentary value. Therefore, great efforts are made to store and preserve such *existing images* in the best way. Another problem is how to ensure the longest possible life for *newly made photographic documents* that are judged worthy of preservation.

Three fundamentally different factors influence the life of a photograph [402]:

1) Properties of the material itself
2) Processing
3) Storage conditions

In the case of historic photo documents, only the storage conditions can be controlled; the processing and choice of material were established long ago.

Optimal storage conditions can generally be described as follows: the rates of possible destructive chemical reactions are decreased by lowering the temperature and the access of harmful reactants is hindered. The most important reactant is water in the form of atmospheric humidity.

Processing must be carried out so that no residues of processing chemicals that could act as harmful reactants over a long time interval are left in the photographs. Special care should be taken with regard to thiosulfate from the fixing bath.

Materials differ in lifetime, chiefly in that silver images are much more stable and nonsilver materials, such as color photographs, are significantly less stable. Although even a gelatin – silver emulsion can be attacked, for example by bacteria or fungi more concern should be focused on emulsion support materials such as glass, cellulose acetate, cellulose nitrate, polyester, paper, and polyethylene. In color, diazo, and vesicular materials, (diazo and vesicular materials, see → Imaging Technology, Chap. 2.3.) on the other hand, the image substances are more important, especially the dyes [40].

Experience – mostly unpleasant – with stability is reflected in the provisions set forth in *standards* for storage conditions [403–405], processing [406], stability and materials for archival purposes [407–413]. These standards are checklists for the prevention of known harmful effects [40].

6.4.2. Storage

Stability specifications for photographic material are classed according to use. For example, documents of *archival quality* (to be preserved forever or for as long as it is at all possible), materials with *long-term stability* (up to about 100 years), those with *medium-term stability* (to 10 years), and *working copies for everyday use* are distinguished [402].

Working copies do not come within the scope of the standards. They are continuously used up, chiefly by mechanical damage due to handling. Familiar examples are exhibition prints of motion pictures and frequently-used microfilms, which become unusable because of scratches and dirt.

The intermediate levels of *medium- and long-term stability* are defined by laws that require stated periods of time for which materials must be stored (e.g., microfilmed business documents or medical X-ray photographs of significance in insurance cases). The periods differ from country to country.

The reason for these different storage periods is that protection of documents against harmful effects, which is necessary for long-term stability, is incompatible with ready access to the stored information. A feasible compromise between quick access and permanence must be found, in keeping with the intended use of the material. Corresponding to the three materials specifications are two *quality levels* of storage conditions: long-term storage for archival materials and long-term (to 100 years) stable documents, where access is difficult, and medium-term storage for continuing use, with the possibility of rapid access. This level of storage, less tightly restricted, is to ensure the survival of documents for the medium term, up to about 10 years.

The provisions of the standards aim to keep harmful volatile substances away from the archived photographic materials. Such substances include SO_2, H_2S, nitrogen oxides, H_2O_2 and organic peroxides, vapors of volatile acids, atmospheric humidity, and atmospheric oxygen [39], [40]. For this reason, requirements on filing enclosures, storage housings, and storage areas are specified. Separate provisions govern air conditioning, safeguards against fire and water, and the handling and inspection of documents in the archive under an established statistical inspection plan [403–405], [407–409], [411].

Storage Areas. Storage areas for long-term storage differ from those for medium-term stor-

age in that they must be separate from all workrooms, such as those for inspection or processing of films. Provisions relating to fireproof building materials and safeguards against water damage due to leaky pipes or floods (but also due to fire-extinguishing sprinkler systems as well as condensation on ceilings and walls when the outdoor temperature is low) are the same for both types of rooms. Finally, vapors and reaction products (e.g., peroxides) of unsuitable ceiling, wall, and floor paints can endanger the stability of stored photographic documents [414].

Storage Housings. The same warnings as to paints and coatings apply to storage housings in the storage rooms, such as shelving, cabinets, file drawers, and racks [414]. Open shelves and racks are permissible only for archived objects in closed containers. Enclosed cabinets must have vent openings if the rooms are air- conditioned to maintain the recommended atomospheric conditions. Storage housings must allow air circulation on all sides without impairment of the protection they afford against fire and the action of firewater.

The *materials* used for storage facilities must be at least fire-resistant; for long-term storage they must be entirely nonflammable (DIN 4102 part 1, class A 1). Anodized aluminum or stainless steel is recommended. Nonstainless steel can be used only with good surface protection. Materials such as wood, pressed board, plywood, hard board and particle board should not be used, not only because they are flammable but also because they release active agents that can fade the photographic images over a period of time [415]. In particular, formaldehyde from glues used in wood products is considered suspect; it is thought to be oxidized by atmospheric oxygen through peroxide and hydroperoxide intermediates to formic acid forming hydrogen peroxides as byproduct. Hydrogen peroxide oxidizes the silver image, converting it to silver formate in the presence of formic acid, which is soluble and diffusible in water that is absorbed even by dry gelatin in equilibrium with the humidity of the air. The result is bleaching of the silver image and possibly, if traces of H_2S are present, a general increase in fog.

Filing Enclosures. The selection of materials for filing enclosures (i.e., folders, pouches, sleeves, boxes, envelopes, jackets, tubes, film cores and reels, cassettes, magazines, film cans) is based on the same principles as that of storage housings. Selection of suitable materials, however, is especially critical because they come into intimate contact with the images [416].

In particular, folders, sleeves, window mounts, slide mounts and aperture cards made of wood-fiber paper with acidic alum sizing should not be used. The autoxidation of lignin in such papers yields agents that can damage photographic images. The specification for suitable wood-free papers includes a content of > 87 wt % α- cellulose, a pH of 7.5 – 9.5 for contact with black-and-white films and a pH close to 7.0 for contact with color films, and an alkali reserve of at least 2 wt % (e.g., through the use of calcium carbonate as filler). Such papers must be free of wood or metal particles, waxes, plasticizers, and other fillers.

Adhesives and tapes used to close sleeves and envelopes must also be chemically stable and free from active decomposition products (acidic, oxidizing, or reducing). Glues based on photographic gelatin, poly(vinyl acetate), and cellulose esters are acceptable; rubber-based cements are not suitable because of autoxidation products. The same holds for printing inks, because experience shows that they often contain unknown ingredients which can cause the formation of microscopically small colored dots on microfilms [417]. This is the reason why B & W paper prints should not be stored in the same envelope with newspaper clippings, even though this might be desirable in terms of subject [418].

Suitable materials for *cores, spools*, and *cans* used to store films in roll form are noncorroding metals such as anodized aluminum and stainless steel. Nonstainless steel can be used only with good surface protection, such as enamel, tinning, plating, or coating, but only with lacquers that do not release decomposition products. Larger rolls, for film lengths of ≥ 150 m, should be stored flat, with the core axis vertical, so that the weight of the whole roll is not imposed on a small bearing area; thus adhesion due to the pressure can be avoided.

Plastics that are best for protective enclosures (e.g., spools, cans, envelopes, bags, jackets, and slide mounts), consist of the same material as the base of the photographic material (e.g., cellulose acetate, poly(ethylene terephthalate), or polyethylene). Other plastics may also be suitable, but practical experience is lacking in most cases.

Definitely unacceptable, on account of chemical instability, are chlorinated plastics, cellulose nitrate, and celluloid as well as plastics containing plasticizers, residual solvents, or peroxides, and foamed polyurethane plastics.

Environmental Conditions. Even in the absence of decomposable materials whose products damage the images, environmental conditions in storage have a strong effect on lifetime. In general, low temperatures and low relative humidities extend the storage life. For the sake of easier access, temperatures and relative humidities may be higher when a medium-term storage life in the 10-year range is needed rather than when true long-term storage with a target life of 100 years (or longer if possible) is desired.

At relative humidities $> 60\,\%$ or temperatures $> 20\,°C$, the danger of fungal or bacterial attack on the gelatin is possible. Even for *short periods of time*, the peak temperatures should not be allowed to go above $32\,°C$. For accessible, *medium-term storage* of color films with chromogenic development, temperatures $< 10\,°C$ are desirable; $< 20\,°C$ is acceptable for B & W films because of the greater stability of the image substance. For *long-term storage*, the relative humidity should be lower than $60\,\%$; the proper value differs somewhat from one material to another, but ca. $30\,\%$ R.H. can be taken as an average value for the storage of various materials in the same room. Again, the temperature for B & W materials should be $< 20\,°C$, but for color materials the limit should be set at $\leq 2\,°C$. These conditions can scarcely be maintained without air-conditioning in the storage room. A special warning is given with respect to the use of cool cellar rooms as storage areas. The relative humidity can reach almost $90\,\%$ if there is air exchange with the surroundings in hot summer weather. The difference in temperature between storage areas and workrooms necessitates a warm up period in the packaged condition in order to prevent condensation of water on archival photographs when they are used, processed, or inspected. Short-term cycling of temperature and relative humidity should be avoided during these operations as well as when the materials are in storage. Films for photogrammetry (i.e., extraction of geometrical data from stereophotographs, mostly used in cartography) and for photofabrication respresent a special case in this respect. In order to retain their dimensional stability, such films must have the same standard atmosphere ($23\,°C$ and $50\,\%$ R.H., as provided in ISO 554-1976) during storage and use so that adaptation processes do not take place. Climate-protected packaging is recommended for the shipping of such films.

Conditioning. Apart from films for photogrammetry and photofabrication, further protection of films that are seldom used can be afforded by conditioning at equilibrium with air at the lower limit of the recommended relative humidity, and sealing the film. Moisture-tight enclosures include cans for film rolls; such a can is sealed with adhesive tape and heat-sealed into a foil bag. For sheet materials, a double-bagging technique is used: two foil bags, each heat sealed, one inside the other. Packages sealed and protected against moisture in this way are stored with their contents at low temperatures. Before they are opened, they must be warmed up for several hours at room temperature in order to prevent moisture condensation on the archival material.

If suitable air- conditioned storage rooms are available, the sealed containers can be dispensed with. In this case, however, special care must be taken to provide for air purification. A slight excess pressure in the storage room will exclude particulate and gaseous contaminants. If the air is treated in scrubbers or absorbers continuous and careful maintenance of this equipment is required, as well as special care against fungal and bacterial attack. The latter is statistically the most common cause of damage to photographic archives.

A further advantage of suitable protective enclosures is that they protect against fire as well as the action of steam produced from firewater. Silver-based archival materials can survive for several hours in such insulated record containers at a temperature of $150\,°C$ without becoming unusable, provided the seal prevents the entry of firewater and steam. For this reason, stability against degradation and deformation in a four-hour test at $150\,°C$ is a requirement for such insulated record containers.

An important point in long-term storage is the inspection of the materials under a statistical inspection plan that provides for a fairly large amount of samples. A two-year interval is considered acceptable. Inspections should be

performed at shorter intervals when deviation in the temperature and relative humidity from the recommended ranges have occurred. The handling of materials requires special care.

Testing of materials for filing enclosures is carried out by keeping them in close contact with a special detector with a coating of colloidal silver under conditions of 86 % R.H. and 70 ± 2 °C for 15 days [416]. There must be no transfer of structure from the enclosure material to the detector and the mean fade value of the detector must not be greater than the control value. As a control test, the same procedure is performed with the detector in contact with paper having a pH between 7.0 and 7.7, e.g., Whatman no. 1 filter paper.

6.4.3. Processing

One effect from which photographic materials cannot be isolated, is that due to the chemicals used in processing. These are removed as far as possible by intensive final washing [419]. As the last processing bath used with B & W materials, the fixing bath is critical [406]. Residual thiosulfate (hypo) was identified as a cause of the instability of photographs soon after the discovery of fixable silver halide materials [420], [421]. The quality of processing, especially the final washing is checked on representative samples by determination of the residual thiosulfate in the freshly processed material [406].

A suitable method is the photometric determination of the concentration of methylene blue in an extraction solution. This dye is formed by reaction of sulfide sulfur from the thiosulfate ion and *N,N*-dimethyl-*p*-phenylenediamine under standardized conditions.

A less specific method is the photometric determination of the iodine consumption in the iodine-starch inclusion compound with which an extract of the sample material is reacted. Both tests are not very useful in the case of aged materials, because part of the residual thiosulfate originally present has already been converted to other products by air oxidation. Instead, the increase in density in regions of minimum density is evaluated in representative samples after treatment with excess $AgNO_3$ solution has produced a silver sulfide fog. In this method, conversion products such as polythionates and sulfide are determined along with thiosulfate; the threshold of detection is not, however, as low as in the photometric dye determination [406].

A complementary test involving treatment with excess sulfide solution provides information about residual, unfixed silver salts in the archival material [406].

The test for effectiveness of final washing will become more important if environmental considerations make it undesirable to extend the final washing (make it longer and more intensive, with greater water consumption) beyond what is actually necessary.

For silver images that are to be safeguarded in an archive for as long as possible under carefully controlled storage conditions, the thiosulfate content must be as low as possible. The level is limited by the thickness of the gelatin layer, which always retains small amounts of thiosulfate.

In 1986 studies showed that a very small residue of thiosulfate can actually enhance stability under storage conditions not corresponding to recommended archival quality [422–424]. Such conditions apply to areas where peroxides and hydrogen peroxide may be present. It is thought that sulfide is released by the thiosulfate, forming a protective coating of silver sulfide on the image silver and thus guarding it against peroxide attack. A sulfide toning of the finished image after processing has a similar stabilizing effect on the silver image [425], [426]. The introduction (from baths) of substances such as thiocyanate, aminoguanidine, etc. [427] that intercept peroxides, also improves stability. This is recommended, e.g., for photographs that will be placed in display windows in inner cities where automobile exhaust concentrations are high.

6.4.4. Materials

When amateur photography got under way (Eastman Kodak), and especially after the invention of cinematography, original exposures were made on films with cellulose nitrate as support. A substantial body of photodocuments, especially historic motion pictures and newsreels, still exists on this base.

Because of the inherent instability of the cellulose nitrate base, the outlook for the survival of these historical documents is not good. Even

without fires, in which case this material cannot be saved, the autocatalytic degradation of celluloid cannot be prevented indefinitely. The degradation product nitric acid also attacks the silver image in the emulsion. In most cases, however, rolls of this film agglomerate into inextricable lumps when the base softens by the decompostition of cellulose nitrate [39].

For these reasons, a number of film archives have continuing programs with the aim of at least recopying the information onto safety film. The authentic originals are discarded; their disposal is governed by the safety precautions applicable to explosives [428]. Because of the nitric acid and nitrogen oxides given off which attack silver images, it is not even permissible to store films on safety bases [such as cellulose acetate or poly(ethylene terephthalate)] in the same rooms where films on cellulose nitrate base are present [429–431]. Cellulose acetate can also undergo hydrolysis with acid and alkaline catalysis. The rate of hydrolysis is a minimum at ca. pH 5. Because of the acetic acid released in this process, the pH drops when hydrolysis occurs. In a slightly alkaline environment, the result is an initial gain in stability, but if the environment is acidic at the start of degradation the process is accelerated by autocatalysis [432].

Another parameter affecting the rate of hydrolysis is the degree of acetylation. The lower the initial degree of acetylation, the faster the hydrolysis. The "vinegar syndrome" is known from experience in archives holding cellulose acetate materials [433]; the cellulose acetate base decomposes to a powder with a strong vinegar odor when film cans of foil bags are opened.

No such experience has yet been obtained with polyester bases, since storage times for this more recently introduced film base are still far shorter. A problem relating to the storage life of these films is the failure of adhesion of the gelatin layer under conditions of cycling humidity.

Testing of Film Bases. The suitability of emulsion supports for archival storage is tested in quality tests. Relevant properties include the *folding endurance* in cellulose acetate and the *tensile strength* and *percent elongation at break* in polyester, especially the impairment of these properties in high-temperature accelerated aging tests in comparison to samples that are not heated [407].

In addition, the *acid value* and the *viscosity* of solutions of isolated base materials are used as a figure of merit, as are the changes in these figures after accelerated aging of representative samples. For polyester bases, the adhesion of the emulsion is tested after cycling between high and low humidity. Pollakowski investigated many vinegar syndrome incidents with cellulose acetate-based films and found that subbings based on cellulose nitrate had been used [433]. These subbings were common until quite recently [434]. Because this cause could not be proved in some vinegar syndrome cases, there is still controversy as to whether noninduced, "spontaneous" hydrolysis of the cellulose acetate had taken place or whether the decomposition had perhaps been due to storage for some time in the same room with nitrate-based films [432].

Print Materials. No cases of damage due to instability of the emulsion support have been noted for prints on the classical material, baryta-coated paper. Wood-free paper used for prints does not show the decomposition that is known in wood- containing, alum-sized book papers of similar age. In the case of polyethylene- coated papers for rapid processing, there are instances where the resin coating, especially on the emulsion side where the coating is filled with the white pigment titanium dioxide, has shown brittleness, blistering, or fibrous splitting.

Damage has occurred, in particular, to exhibition prints that were exposed to light. Similar damage patterns have been produced in accelerated aging tests with high illumination, elevated temperatures, and cycling between high and low relative humidity [435].

In images of the *gelatin – silver type,* the image layer proper – the gelatin layer with the silver image distributed in it – has generally proven to be the more stable component provided the materials were correctly processed and harmful external effects (bacterial and fungal attack, moisture, hydrogen peroxide, organic peroxides, nitrogen oxides, etc.) were averted; however, the useful lifetime is limited by the emulsion support [436]. The stability of negatives on fragile *glass plates* is thought to be similar to the image layer proper under normal storage conditions,

the expected life of glass is longer than that of the other bases [405].

The situation is different for *color photographic materials*. Here the dyes in the image layers are inherently less stable than the support. Dye stability has improved markedly as the technology has developed, but this process can by no means be considered completed.

In the case of color photographic documents worthy of archival preservation – whether still photography or motion pictures – it is therefore recommended to prepare black-and-white separations on silver – gelatin material for archival purposes. The method used is the same as in the making of plates for four- color printing or in the production of color films by the Technicolor process [437].

The preservation of original color photographs and color films can also be useful if their limited life is kept in mind. The same principles of storage apply here as for silver images: low temperature and low relative humidity, or conditioning at low humidity and storage in sealed containers. But effects on the condition of color documents due to the storage conditions are expected to become perceptible within a human lifespan.

Improvements in the storage life of processed color images have resulted from the adoption of better couplers, which form more durable dyes in the photosensitive material [438][439][440]. Approaches to extending the useful life of exhibited color photographs, where photochemical decomposition governs the lifetime of the image dyes, include the incorporation of UV absorbers in the image layers and in protective overcoats. Both quality attributes – the dark or archival lifetime and the light or display stability – of modern color materials result in lifetimes that are longer than the time span required to launch improved product generations on the market [441]. Practical experience relating to storage life therefore cannot be employed in improving the storage qualities of new product generations, for example in selecting better couplers [410], [442]. Time-accelerated tests are needed for this purpose in which the processed material is subjected to more drastic conditions than will occur in its practical use. Life expectancies deduced from these tests should be regarded as highly theoretical. With regard to light stability, the bleaching of color densities and the yellowing of whites under intense illumination imply that similar color shifts will take place under conditions of low illumination that occur in practice [443]. As a first approxiamtion, equal effects are assumed to result from equal exposures.

For purposes of practical testing, a draft standard [410] sets forth increases in illuminance that differ from one material to another.

Archival tests involve time-accelerated tests at elevated temperature. The assumption is that the mechanism of the reactions leading to changes in color density will not change in the range between the storage temperature and the test temperature. The effect is quantified with the Arrhenius equation [444]:

$$\log k = \frac{\Delta G^*}{RT} + C$$

where k is the rate constant, $\Delta G*$ is the free energy of activation, R is the universal gas constant, T is the absolute temperature, and C is a constant of integration. This relationship also decribes reasonably well the behavior of older photographic dyes in a period of up to 10 years [442].

For the selection of image dyes in practice, it can be assumed that if two dyes have the same extrapolated life expectancy, the one with the lower free energy of activation $\Delta G*$ and the lower temperature coefficient of color-density decrease will have a high probability of being the better. In other words, this test selects the dye that is also more stable at low temperature. There is an increased probability that a competing reaction (with a lower free energy of activation) will become rate-determining at lower temperature, if the measured free energy of activation in the high-temperature test is higher. The presumed reliability of the extrapolated life expectancy increases as the lower value of the experimental temperature range declines, that is, as it becomes closer to room temperature. But this criterion implies a longer experiment. The draft standard [410] proposes at least four temperatures in the range $55 \pm 0.5 - 95 \pm 0.5$ °C; the span should be at least 20 °C and preferably larger. The recommended relative humidity is 50 ± 3 %. Higher and lower humidities are permitted if special humidity values are expected in use or in storage [440], [445]. R.H. values above 60 % should be avoided in the high-temperature test, because the properties of some constituents of the image lay-

ers, especially the gelatin, change abruptly when the humidity rises above ca. 60 %. This can lead to changes in the reaction mechanism, which do not occur under service conditions.

7. Nonphotographic Properties and Their Measurement

Both photographic film materials and photographic papers must resist damage from the stresses they experience during processing and use. A variety of loads are applied, beginning with cutting, perforation etc, at the packaging stage. Films are then subjected to partly discontinuous stress during transport and may fracture, especially in very dry climates when they give up water and become more brittle. Conversely, when films absorb water, for example, in tropical countries, they may adhere to materials in contact with them.

In processing, emulsion layers swell in the aqueous baths and suffer dramatic losses of strength. Nevertheless, films and papers being transported through processing machines must not receive scratches from the conveying and deflecting rollers or from the doctor-blade arrangements used to remove liquids from the surface of the emulsions. Hardening of the gelatin during the manufacture of photographic materials is the decisive factor for the increase in mechanical strength (see also Section 3.1.4.1).

7.1. Hardening

The gelatin binder, if not hardened, swells strongly in the processing solutions and has little mechanical strength, in addition, gelatin melts at ca. 25 °C. For these reasons, hardeners are added to emulsion layers: i.e., compounds that cross-link the polypeptide chains. These hardening agents should be as photographically inert as possible.

Processing, especially with the high-speed, high-temperature automatic methods currently used, imposes severe requirements. It is relatively easy to cross-link gelatin molecules to varying degrees, so that photographic emulsions can be selectively hardened. The degree of hardening, as expected, influences the sensitometry: hardening reduces the sensitivity and gradation, restrains the development kinetics, and diminishes the granularity. The swelling factor Q = thickness of wet layer/thickness of dry layer serves as a measure of hardening. It has a value of ca. 3 for films and 4 for printing materials.

Photographically inert compounds, both inorganic and organic, can be used as hardeners. For example, chrome alum and aluminum alum cross-link gelatin at the free carboxyl groups. On the other hand, organic compounds react chiefly with the free amino groups, examples include [19]:

1) Aldehydes, e.g., formaldehyde, glyoxal, glutaraldehyde
2) Aldehyde acids, e.g., 2,3-dichloro-4-oxo-2-butenoic acid
3) Diketones, e.g., diacetyl
4) Dihalides, e.g., 1,3-dichloropropanol
5) Compounds with activated double bonds, e.g.,divinylsulfones, *N,N′,N″*-trisacryloylperhydro-s-triazine
6) Diisocyanate – bisulfite adducts
7) Bisepoxides
8) Bisaziridines
9) Dichlorotriazine derivatives, such as 4,6-dichloro-2-hydroxy-5-triazine

Examples of substances that react with the peptide groups are: (1) carbodiimines, (2) *N*-carbamoylpyridinium and isoxazolium salts, (3) esters of 2-alkoxy-*N*-carbonyldihydroquinolines, and (4) chloroformamidinium salts.

Hardeners can be added to the emulsion just before coating if the hardening reaction goes slowly enough. Fast-reacting substances, must be applied as a separate gelatin-poor overcoat. Since the mid-1980s it has become possible to integrate instant hardeners(i.e.,hardeners whose action goes to completion in < 4 h) into all other layers.

7.2. Dry Properties

The mechanical properties in dry climatic conditions are determined by the properties of both the emulsion support and the emulsion. The water contents in the various elements of the emulsion play an important part. Table 10 gives a summary [34].

Table 10. Moisture capacity (wt %) of some film components at different relative humidities

	Relative humidity of air, %		
Material	30	50	70
PETP	0.12	0.2	0.4
Cellulose triacetate	0.9	1.4	2.4
Emulsion	5.9	8.1	12.0

The water content shows relatively little dependence on temperature but water absorption and desorption is complicated by hysteresis. For example, pure gelatin absorbs ca. 15 % water when the relative humidity is raised to 50 % from the dry side but ca. 17 % when it is decreased to the same level from the humid side.

7.2.1. Brittleness

Photographic materials are generally fairly flexible. Problems can occur at low moisture contents and low temperatures. For example, the film may break in the camera, or in the finishing laboratory after films have been spliced. The film may break in the emulsion support (triacetate or PETP), or cracks may develop in the emulsion. This can happen if, the film, for instance is rapidly drawn over small rollers with the emulsion side out, so that the emulsion is stretched. This kind of takeup mechanism is mainly used in newer cameras. In order to prevent fracturing, plasticizers are added to the gelatin; examples are polyethylacrylate, polyacrylates, and polyurethane latices.

Testing Methods. Methods that have been introduced for measuring brittleness can only approximately simulate the realistic situation.

The *wedge brittleness* test is used for film [446]. Strips of film are pulled through a wedge, emulsion side out, under well-defined dry climatic conditions (20 or 30 % R.H.). The length of the fragments gives the fracture radius. Other methods exist, such as the *folding endurance test* [447], in which well-defined flexural oscillations are counted up to failure, or the *parallel-jaw brittleness tester* [448]. In the last apparatus, film loops of specified length are stretched, emulsion side out, between two parallel jaws that move at a specified speed to break the sample. The device makes it possible to determine the fracture diameter and breaking strength.

The brittleness of films depends on the filler content of the gelatin binder; silver halide grains in particular degrade this property. In addition, the drying of the film during manufacture is important; the cooler and slower the drying process, the more flexible the film will be.

7.2.2. Curl

As was pointed out in Section 7.2.1, a photographic film or paper absorbs or releases moisture depending on the ambient conditions. Gelatin swells on absorbing water, and the resulting forces curl the film or paper. Conversely, in a dry climate gelatin gives up water, and tensile forces are produced that again can lead to curl. Expansion or shrinkage is greater in the emulsion than in the base. Along with the water balance, two other factors are important in curling: (1) the initial curl applied to the base (see also Section 3.2) by special manufacturing processes, and (2) cold creeping, especially of PETP, when the material is wound on small-diameter cores (core setting). Severe curling leads to problems in the camera (sharpness) or in finishing.

Curl Measurement. Curl is measured as set forth in ISO 4330 [449]. Film specimens as described in the standard are acclimatized at $23 \pm 2\,^{\circ}\mathrm{C}$ and 15, 30, 50, 70, and 85 % R.H.; then a quantity such as the bow height in mm is measured. The curvature $1/R$ (R in m) is then calculated or determined with prefrabricated templates. A flat specimen accordingly has an infinitely large radius R. The curvature value $1/R$ is prefixed with a + or − sign, + if the emulsion is inside (curl toward the emulsion) and − if the emulsion is outside (curl toward base).

7.2.3. Dry Adhesion

Special subbings have been devised in order to control the adhesion of the emulsion layers and any backings that may be present (on roll or sheet film) on the base before and after processing (see also Section 3.2.1.3). The layers must remain adherent even on climatic changes.

The measurement or test is covered by standards [450], [451]. Specimens are conditioned

for ≥ 15 h at 23 °C and 50 % R.H. A strip of adhesive tape ca. 15 cm long is applied to the test specimen with the most uniform possible pressure; one end is left free as a grip. The specimen is held on a flat surface and the tape is rapidly pulled off with its free end at an angle of 180 °C. If the adhesion force is to be sufficient, it must be at least 9 N for an adhesive tape 1 cm wide. An acceptable film will show no material pulled loose from the emulsion side or the back. As a rule, the specimen is scored in a checkerboard pattern before the test.

There is also a humidity-cycling adhesion test. Specimens are held, hanging freely, through 12 cycles each consisting of 8 h at 50 °C and 96 % R.H. followed by 16 h at 50 °C and 11 % R.H. They are then examined to see whether parts of the layers have become loose, peeled off, or separated.

7.2.4. Dimensional Stability

The dimensional stability of photographic materials is not so important for amateur products but very much so for professional ones used in the graphic arts or in aerial-survey photography. Such materials should exhibit the smallest possible changes due to moisture, temperature, processing, and aging. Possible consequences of such changes include the registration problem in color printing.

From this standpoint, PETP is better than cellulose triacetate, for the PETP base has a smaller coefficient of thermal expansion as well as a smaller coefficient of expansion due to moisture [361].

Dimensional stability is measured as given in ANSI [452], DIN [453], or ISO standards [454]. Changes in length are determined to the best precision possible, generally with a measuring microscope. The specimens are measured before and after a high-temperature moisture treatment or processing. The coefficient of linear thermal expansion is stated in $\mu m\, m^{-1}\, K^{-1}$, and similarly the coefficient of expansion due to humidity in $\mu m\, m^{-1}\, \%^{-1}$ (where % implies relative humidity in %). For the processing test, the change is simply stated in $\mu m m^{-1}$.

7.2.5. Friction

The frictional behavior of photographic films and papers must be appropriate to the application. For example, miniature films and motion-picture films must not cause transport malfunctions in the camera. These films have extremely thin wax coatings or dispersed silicone oils on the emulsion surface and, in some cases, on the back. Such treatments also improve the resistance to scratching. A photographic paper should have enough friction to prevent its escape from the rollers and keep stacks of material from collapsing. In order to reduce the contact areas and prevent adhesion between emulsion side and back, for example in miniature films, plastic spheres (1 – 10 µm in diameter) that are soluble or insoluble in the developer are added to the protective overcoat. Roughly half the diameter of these spheres protrudes from the topmost layer.

For photographic materials in general, the static and kinetic coefficients of friction are complicated functions of temperature, moisture content, and pressure. For example, the gelatin binder becomes tacky above 70 % R.H., and friction increases markedly.

Naturally, the simulation of practical conditions in testing is difficult. There are numerous methods that (sometimes in combination) give a good approximation. The determination of static and kinetic coefficients of friction is governed by DIN 15 586 [455] and ASTM-D 1894 [456]. A sled of specified size and a mass of 200 g is pulled over the contact partner and two force measurements are made: (1) the force required to "start" the motion and (2) the force needed to keep the sled moving at constant speed over the specimen. Measurement (1) yields the static coefficient and (2) the dynamic coefficient of friction. In each case the coefficient is the ratio of the measured force to the normal force (weight of the sled). The sled can be covered with any materials that come into contact under practical conditions. The test can also be done with the sled stationary and the contact partner moving; the results are the same. The DIN standard provides for testing on an inclined plane; the quantity measured is the angle at which the specimen begins to slide. There are other methods as well. For example, the forward and reverse transport forces in cameras can be measured.

Other standards apply to the determination of film pullout force for photographic films in miniature cartridges [457], [458]. After acclimatization of the film in the cartridge under stated conditions, the film is inserted into a gauge (weight 2.5 N) and the free end is pulled vertically upward. The gauge must not be picked up from the floor.

7.2.6. Dry Abrasion

Photographic materials have little resistance to scratching. Abrasion is harmful especially when films are to be enlarged. This means that films and work areas must be kept very clean. Some improvement can be achieved by adding oily substances, such as emulsified silicone oil, to the protective layers. Such additives also reduce friction (see also Section 7.2.5).

The measurement of scratching resistance is described in standards [459], [460]. The specimens are mounted flat on a smooth surface. The holder is moved either manually or by motor. Scratches are made by a sapphire rod with a radius of 75 µm held in a counterbalanced arm loaded with weights from 0.1 to 10 N. The test is done on acclimatized specimens. The test result states the force in N at which the first scratches visible to the naked eye in obliquely incident light are produced. The greater this weight, the better is the protection against abrasion. Typical values for emulsions are 0.5 – 2 N.

In addition to this visual examination other methods of assessment can be used depending on the application of the film, for example by projection or in a film scanner.

7.3. Wet Properties

As already mentioned, photographic materials can also suffer damage from roller-transport systems or stripping devices in processing, when they are wet and swollen. In particular, since 1972 advances have continued to shorten processing times and raise processing temperatures, imposing added mechanical stresses on the materials. For the manufacturers of photographic materials, this has meant that improvements in wet properties are also needed.

7.3.1. Swelling

Emulsion layers must swell in processing in order to facilitate the necessary diffusion processes. For example, fresh developers, bleaching chemicals, and fixers must be able to enter the emulsion, while reaction products such as bromide or silver complexes from fixation must be able to diffuse out of the film. The degree of swelling depends not only on the hardening of the layer (see Section 7.1) but also on the salt load and the pH of the processing solutions. Finally, the drying of the photographic material plays a role [1]. The emulsion experiences not just vertical but also lateral swelling. This lateral swelling, however, is hindered by adhesion to the base. The stresses produced can curl the material. When the degree of swelling is sufficiently high (i.e., ca. 3), however, the modulus of elasticity becomes small, and so the stresses are low too. The performance of the base (precurl) is then dominant.

There are many techniques for determining the degree of swelling or the swelling factor (for a definition of swelling factor see Section 7.1). The simplest method is weighing. Stripping off the "surface" water is a problem in this approach. Other methods are described in [9]. For example, the static pressure between two parallel plates with the swelling material between them can be used to determine the swelling height [461], [462]. Or a probe can be lightly pressed against the swelling surface and precision distance sensors can be used to measure the swelling height. These techniques can also be performed at intervals so as to determine the kinetics of swelling (as in the static-pressure method). In order to arrive at the swelling factor, the dry layer thickness must be determined, for example on a microsection examined under the microscope. Typical swelling factors are ca. 3.

7.3.2. Wet Abrasion

When photographic materials have swollen in the processing baths, they are very sensitive to surface damage.

Wet abrasion behavior is determined similarly to dry abrasion; the test is governed by an

ANSI standard [463]. The abrader is again a sapphire, but now the radius is larger, $r = 0.38$ mm. The weight ranges continuously from 0 to 5 N and can be further increased with supplementary weights. Measurements are performed in temperature- controlled water or processing solutions after specified times have been allowed for the specimen to swell. Producing the first visible damage requires a weight of ca. 0.5 – 1 N.

7.3.3. Reticulation

A photographic material may have up to 15 thin layers, which differ greatly in the contained ballast (silver halide, coupler, oil former, etc.). Such structures can be treated as laminates. The lateral swelling tendency of the emulsion layers can generate stresses that differ between adjacent layers. Cracks may result, and these may affect image quality. The danger of reticulation diminishes with increasing hardening.

7.3.4. Wet Adhesion

The wet abrasion resistance described in Section 7.3.2 strongly depends on the wet adhesion. Determination of wet abrasion resistance is meaningful only if the wet adhesion is adequate. The test is a primitive one: After the specimen has had a sufficient time to swell, the emulsion side is scratched with a cross-shaped stylus, then rubbed with a finger or a rubber stopper, and afterwards examined to see whether the emulsion layers have separated at the scratched mark. As a rule of thumb, the adhesion between emulsion layers is poor if one or more of the layers contain too little binder (≤ 45 vol % gelatin).

The subbing also contributes to adhesion between emulsion layers and the base. Everything mentioned in Chapter 7 about the dry and wet properties of emulsion layers also applies to backing layers when these are used, as in roll and sheet films.

8. Photographic Materials and Applications

8.1. Photographic Plates

Photographic emulsions are currently coated on paper or film base. Such flexible materials in roll form are easier to handle during production, packaging, and use. Modern supports also have excellent physical properties (see Section 3.2.1.1). During the first hundred years of photography, *glass plates* were more popular because of their availability, flatness, and dimensional stability. Except for paper, no flexible supports existed. Today, glass plates are employed only when the requirements on dimensional stability are extremely rigorous; this is almost exclusively the situation with scientific and technical applications. Most plates have a simple coating structure: subbing, emulsion, and protective overcoat.

Photography has always been a useful tool for scientific observation. For example, UV radiation was discovered as early as 1801 by exposing a paper coated with silver chloride to the light emerging from a prism.

Holographic Plates [464], [465]. The discovery of holography and the laser opened up a new field of application for photographic plates. Plates for this use must have extremely fine grain. Their micrate emulsions have grain diameters of 30 – 90 nm, high contrast ($\gamma = 5 - 8$), and extremely high resolving power (up to 3000 lines /mm). Their spectral sensitivtiy must be matched to the radiation from a variety of lasers (514.5 nm for argon, 694.3 nm for ruby, or 632.8 nm for He – Ne lasers).

Suppliers. Agfa – Gevaert (Holo-test) and Eastman Kodak (H.R. and Holographic Plate) supply an assortment of photographic plates for holography, but general-purpose high-resolution plates from the technical lines are also used.

Mask Making (→ Imaging Technology, Chap. 4.2.2.). Exposure masks for the fabrication of printed circuit boards and microelectronic devices are sometimes produced by the silver halide process. Such plates are of high

resolution. However, most masks are made with photoresists.

Spectroscopic Plates [465], [466]. Spectroscopic plates, with spectral sensitization ranging from the UV to the IR, are employed for the detection and recording of visible and invisible radiation. Originally these were used for spectrography. After the introduction of recording spectrophotometers, their application shifted to more general work. Speeds are in the low to middle range for camera use and can be varied somewhat through the processing technique.

The gradation ($\gamma = 0.8 - 4.0$) ranges from normal to ultra-hard; an effective antihalation protection is required. Special low-gelatin- content plates are used for the UV. Ultraviolet plates are sensitive to $\lambda \geq 200$ nm; Schumann plates to $\lambda \geq 180$ nm. Infrared plates are generally sensitive to thermal radiation and must therefore be stored at low temperatures.

Suppliers. The main suppliers of these special materials are Agfa – Gevaert (Sciencia) and Eastman Kodak (Spectroscopic Plate). Similar plates are avialable for photomicrography and electron micrography.

Nuclear Plates [467–469]. Nuclear plates were important in nuclear research and technology, where they found use in the detection of elementary particles and in the recording of the tracks left as they passed through the emulsion, interacted with other nuclei, or decayed (Fig. 86). These studies stimulated the understanding of elementary matter.

Many scientists in this area prepared their own emulsions. There was an intense exchange of knowledge about interesting and unconventional methods of preparation, and the effectiveness of the resulting materials.

Nuclear track emulsions are very silver-rich (ca. 80 % AgBr), have a moderate grain size (0.1 – 0.3 µm), a narrow grain-size distribution, and are not dye-sensitized. The sensitivity is determined by the maximum energy of a charged particle that just leaves a detectable track in the emulsion. The most sensitive grades of track emulsions detect particles of all energies.

The development of other kinds of detectors (cloud chambers, bubble chambers, coincidence counters, etc.) has made nuclear track emulsions much less important.

Figure 86. Decay of a Z^0 particle in a quark/anti-quark as seen in the DELPHI detector (CERN, Geneva)

Autoradiographic Plates [470], [471]. Autoradiographic plates are glass plates that are coated with a thin layer of nuclear track emulsion or another fine-grain emulsion. Often a releasing layer is incorporated in the emulsion. Then, it is possible to remove the light-sensitive layer from the glass support before or after processing (stripping film). A development of the 1980s in this area is the optical or thermal excitation of a phosphor layer (see Section 8.2.5), which is exposed to the radioactive specimen, substituting the photographic plate. The released light can be detected by electronic devices, and digital image processing is possible.

Astronomical Plates [467]. High-speed plates (DIN 17 – 25, ISO 40 – 250) are used in astronomical research. These materials have normal to hard gradation ($1 < \gamma < 1.5$) and a variety of spectral sensitizations (blue-sensitive, orthochromatic, or panchromatic).

The light, often very feeble, is "collected" during extremely long exposure times. Under these conditions, low-intensity reciprocity failure (see Section 2.1.6) becomes a problem and must be held to a minimum through the design of the material or through special processing. Astronomers sometimes employ pretreatment and special processing to push the speed. These plates usually form part of the manufacturer's technical line.

8.2. Films

8.2.1. Films for Professional and Amateur Photography

Color negative, color reversal, and black-and-white films used for still photography fall into a number of sensitivity classes. (For the determination of film sensitivity, see Section 6.1.4 and the following ISO standards: ISO 5, ISO 6, ISO 2240, and ISO 5800). (ISO standards can be obtained through the national standards organizations or directly from ISO).

Low-speed films (ISO speeds from ca. ISO 25/15°–ISO 50/18°) are fine-grained; they have high resolving power and relatively thin emulsion layers and therefore offer excellent sharpness. They are used, especially in professional photography, as originals for enlarging and for images to appear in printed materials.

High-speed films are those with speeds of ISO 800/30°–ISO 5000/38°. They are used for short exposure times under unfavorable lighting conditions (sports, theater, etc.). At the time of writing (1990), films with speeds of ISO 100/21°, ISO 200/24°, and ISO 400/27° are used most frequently.

Table 11 lists the most common sizes and packagings of photographic films. There are standardized film and cassette (cartridge, magazine) configurations which fit the body and transport system of different camera types.

Sheet, roll, and miniature films differ in the coating structure and the thickness of the base. The common base materials are cellulose esters and poly(ethylene terephthalate). Both materials satisfy the requirements of ISO 5438 and ISO 7830 for safety films; i.e., they are not easily ignited and do not burn readily [42]. Cellulose esters are employed chiefly in amateur films. Because of its greater dimensional stability and tensile strength, PETP finds use in sheet and other films for professional users.

Sheet films and roll films 120 and 220 have a nonphotosensitive gelatin backing, which counteracts the tensile forces developed in many photosensitive front coatings. Colored backings are occasionally still used for antihalation protection; such carbon black or dyed coatings must be removed in processing (see Section 3.2.1.6).

Most cellulose-ester-based films have the base slightly gray-colored (gray base) for antihalation purposes. In addition, silver–gelatin or dyed gelatin coatings (in B & W films) are applied as antihalation undercoats below the light-sensitive emulsion layers. These must be bleached or decolorized in processing so as to render the film transparent.

Figure 87 shows several coating structures for photographic films. Today, the sensitive emulsions are usually applied by multiple coating (up to 5 coating operations). A modern color film can have as many as 19 individual coatings (see Fig. 45).

When films in roll form are exposed in the camera, they are wound from a supply chamber to a takeup chamber. Cassette films have both chambers integrated into a plastic cassette. For *roll films* 120 and 220 size, the spool on the takeup side is identical to that on the supply side; after the last frame is exposed, the empty supply spool is moved over to the takeup position.

135 Size miniature films are generally transported, frame by frame, into a takeup chamber with a special permanent takeup spool. When the film has all been exposed, it must be rewound back into the cartridge before it is removed from the camera.

In some *motor-driven cameras*, the film is loaded and then, before exposure, its entire length is transported into the space supplied. As each frame is exposed, the film is rewound into the original cartridge.

In order to facilitate the adjustment of the amateur's camera to the speed of the film loaded in it, cassettes for the 126 and 110 and cartridges for 135 size films bear codes, accessible from outside, that regulate the exposure control in properly equipped cameras and also contain information about the length of film loaded.

Color reversal films are balanced either for daylight (5500 K) or tungsten light (3200 K). Color reversal films for tungsten light are specially balanced for longer exposure times. In contrast, films for daylight are balanced for short exposure times or flash. The manufacturer provides instructions on the use of filters for exact matching to the color of the light source. Most color negative films can be used with all types of illumination. Because of wide exposure latitude (see Section 6.1.2), exposure is less critical with color negative films than with color reversal films. When the negative film is printed on color paper, however, part of the exposure range

Table 11. Common film sizes and packagings for still photography

Film type	Cutting width *W*, mm; minimum length *L*, mm	Image area dimensions	Typical manufacturing and packaging	Dimensions according to ISO standards ∗
Sheet films		65×90 – 300×400	in boxes	1012
Roll films	*W* 61.75	45×60	unperforated film spooled	732, 897

	L 750 (24 expos.)		size 110	

∗ ISO standards can be obtained from the ISO Central Secretariat, Case postale 56, CH 1211 Genève, or from national standard organizations.

Figure 87. Examples of coating structures of photographic films (not to scale)
A) Black-and-white 135-size film (complying with ISO 1007); B) B & W roll or sheet film (complying with ISO 732 and ISO 6407); C) Color negative or color reversal 135-size film (complying with ISO 1007); D) Color positive motion-picture film (complying with ISO 491)
a) Overcoat (0.2 – 1.0 µm); b) One of three emulsions (3 – 12 µm) with panchromatic sensitization (B & W) or spectral sensitization (color films); total thickness of all emulsion layers in color films 12 – 25 µm; c) Silver – gelatin antihalation undercoat (2 – 5 µm); d) Subbing (< 0.3 µm); e) Yellow filter layer (3 – 6 µm); f) UV filter layer (0.5 – 2 µm); g) Gelatin NC backing (colorless or colored); h) Backing with carbon black or dye; i) Base: cellulose esters or polyethylene terephthalate (PETP), usually with a weak gray color (gray base), but occasionally colorless (clear base); thickness 170 – 200 µm (sheet film), 90 – 100 µm (roll film), 115 – 130 µm (films size 135, 126, 110 motion-picture film); j) Antistatic coating (< 0.3 µm)

is lost again. Reversal transparencies are superior to paper prints both in color reproduction and in brightness range; they can be printed on reversal paper (with some loss of quality).

Professional photographers use chiefly large-format sheet and roll films. Often called "professional films," these materials are adapted to the special needs of this user group; i.e., with respect to characteristic curve, Schwarzschild behavior (see page 11), color balance, response to pushing development, or mechanical properties (such as surface texture for retouching).

Color and B & W duplicates are made with reversal copy film or with internegative films

combined with positive films (print films). Print film (packaged as sheet film or 35 mm roll film) can also be used to obtain transparencies from negatives.

8.2.2. Motion Picture Films [472][473]

Camera Films. The professional production of motion picture film is based on a complete negative – positive system including several intermediate steps in order to facilitate editing and printing. 35-mm film has been the main standard material during the last hundred years (Table 12). 70-mm film [474], [475] became a second standard associated with the high-quality projection on wide screens combined with stereo sound. This application started with the introduction of CinemaScope and Cinerama in the 1950s. The use of 70-mm film as camera-sensitive original is, however, quite exceptional today. Most 70-mm copies have been blown up on print film from 35-mm originals. The smaller formats (16-mm and 8-mm) are employed for television commercials and films, educational purposes and amateur motion pictures. After World War II the color motion picture business gained momentum and acceptance. Subsequently black-and-white materials gradually disappeared.

Table 12. Figures of merit of motion picture films

Film width, mm	Frame format (for projection), mm	Speed of projection, frames/s	Film consumption, m/min
35	20.9 × 15.2	24 ∗	27.4
16	9.6 × 7.0	24 ∗	10.9

∗ The projection speed of TV films is 25 or $16\frac{2}{3}$ frames/s.

Motion-Picture Color Negative Film. This material is the basis of a process of several steps with the positive print as a final product. The layer structure is very similar to that of the color negative employed by photographers. However, the requirements concerning color reproduction and image quality are very high because several printing operations must be carried out between the original and the final positive. Moreover, a high image enlargement is usual for theater projection. Therefore every detail, starting from the shape and structure of the emulsion grains (see Section 3.1.1), is carefully controlled. Negative materials for camera use are available in the medium to high-speed range (≥ ISO 100). The lighting conditions in the studios are carefully balanced so that a large exposure latitude is not a necessary condition. The sensitivity is optimal for tungsten light (3200 K). Shooting under real daylight conditions requires a conversion filter. The support material is often cellulose triacetate for convenient editing and splicing.

Reversal Motion-Picture Films. Immediately after processing, reversal motion-picture films give a positive suitable for exhibition. If a reversal image is compared with a copy of a negative film having virtually equal sensitivity, the reversal image is finer-grained and sharper, and also less costly. If, however, a larger number of copies must be made from a film, the negative – positive process becomes more economic.

Black-and-white reversal films in narrow formats are hardly used any more. Color reversal films in these formats often have a back coating of carbon black to combat halation as well as improve the mechanical properties of the film.

Packaging. 35 mm negative motion-picture films are available in 60, 120, and 300 m rolls on plastic cores; 16 mm films, in 30 and 60 m lengths on metal daylight spools and in 120 m rolls on plastic cores. 16 mm films have perforations on one edge or both edges. 8 mm films (Super-8 perforations on one edge) are sold mainly in cassettes containing 15 m of film (DIN 15 823) and, in this packaging, are used chiefly by amateurs. The latter application is being superseded by video recording. The motion picture technique is well established and standards exist for, e.g., materials, formats, treatment, conservation, sound tracks, and film transport.

Sound Recording Films [476], [477]. In professional film-making, the original sound is usually recorded separately on magnetic tape, then synchronized with the scene by the use of sync markings on the film (pilot sound). The sound is then transferred to the film in one of two ways: to a magnetic stripe on the film material (*magnetic sound*) or, in the form of an optical copy, to an optical sound track on the edge of the film (*optical sound*). Because the projected frames are transported discontinuously (one at a time) by employing a loop, the sound must be

scanned continuously outside the loop. Hence, the image and the sound must be offset from each other in the direction of film travel.

The *optical sound track* is created with electro-optic transducers (e. g., Karolus cell), which vary either the track width (variable-area recording) or the image density (variable-density recording). When the copy is exhibited, the track modulates the light flux incident on a photocell.

In the optical sound system, high-resolution sound negative films are used as the intermediate step. In the case of variable-area recording, the film is developed to a steep gradation ($\gamma = 4 - 5$).

In the *magnetic system,* exhibition copies are made on films with magnetic stripes applied at the factory. In addition to the professional copy, direct sound recording on the camera film is possible; this technique is employed chiefly by amateurs. The width and location of the stripe depend on the film format and perforation.

Singly - perforated films have the recording stripe on the unperforated edge; a narrower "balancing stripe" on the perforated edge brings the two edges of the film to the same thickness so that the film will wind evenly on the roll. This second track is occasionally used for sound recording, such as for stereo playback (see Fig. 88).

Figure 88. Arrangement of magnetic tracks in motion picture films
A) Double-perforated film; B), C) Singly perforated film

Both camera films and positive motion picture films (see below) with added magnetic stripe are available in all the usual formats and packagings. The sound track can also be applied in the developing plant after exposure.

Positive Motion Picture Films (Motion Picture Print Films). In the negative – positive process, not only the image quality of the negative but also the fineness of grain, resolving power, and sharpness of the positive film are crucial for the quality of the projected image. Color positive films often have the three dye layers in a different order from camera films; for example, the magenta layer may be on top (see Section 5.2.2.6). This is done to match the material to the sharpness perception of the human eye, which is greatest in the green layer. Fine grain emulsions and incorporated filter dyes are additional factors contributing to the resolution. Positive films are roughly a factor of 10 – 100 slower than camera films. They are developed to a gradation of 2.5 – 3.5. B & W positive films have no antihalation coating. Color positive films have a dye or carbon-black backing. The positive film is exposed in contact with the negative in special motion picture film copying machines, or by optical imaging of the negative (principally when normal-sized negatives are reduced to small-format film).

Packaging. 35 mm width with standard "positive perforation"; 16 mm with single or double perforation. Plastic core, rolls of 300 and 600 m.

Films for the Production of Duplicates. The motion picture industry uses negative duplicates when making exhibition prints, in order to avoid mechanical damage to the original negative in the copying process. Fades and dissolves as well as special effects are produced in the preparation of negative duplicates. The duplicate negative is obtained either by copying the original negative onto an intermediate positive film (interpositive, master positive master) and copying the interpositive onto duplicate negative film, or by copying the original negative onto a duplicate reversal film. From a reversal original, a duplicate negative can similarly be made on internegative film, so that exhibition copies can than be made on print film.

Reversal copying films are also used for making prints from reversal originals. These copying films are developed similarly to reversal films.

Special Films for Television. In addition to negative and positive motion picture films in 35 and 16 mm formats, television uses mainly 16 mm reversal films with gradation and color characteristics especially matched to the scanning properties of television. These special color reversal films can also be used for documentary, instructional, and other nontelevision purposes.

Along with films balanced for daylight, there are those balanced for tungsten light. They have speeds of ISO 50 – 400, but special processing makes it possible to "push" individual film types to three times the nominal speed if some loss of quality is acceptable. In addition to the camera films, there are reversal copy films suitable for TV use.

8.2.3. Reprographic Films

Reprographic Films are described in detail elsewhere (→ Imaging Technology, Chap. 3.1.1.).

8.2.4. Microphotography [478–481]

The idea of photography at a reduced scale was conceived as early as 1850. The systematic microfilming of printed matter, containing alphanumeric and/or graphical information, for documentation and archiving purposes started only in 1920 with the copying of bank checks on 16 mm film. Today, microfilm is a legally accepted storage medium, used in document management systems including computer-aided retrieval (CAR). Replacement of these systems by digital storage media is not anticipated, because of the permanency of the records and the very favorable material costs. Integration into hybrid systems can, however, be expected. A more recent application is computer output on microfilm (COM).

Depending on the specific application and the available equipment, several formats and microimage configurations are in use. Basic forms are film roll, fiche, and aperture card. About 1000 images can be stored on 10 m of 16 mm film. The camera original is almost always on low-speed silver halide material. High resolution and contrast are typical. The resolution can exceed 200 lines/mm, in order to ensure the legibility of the microimage when enlarged by a reader-printer (e. g., 384 lines/mm).

The type of microfilm used depends on the application:

1) For the recording of engineering and other documents, medium-speed films designed for maximum sharpness are generally used.
2) Higher-speed microfilms are employed in high-speed continuous-feed cameras for filming printed documents.
3) For use in COM systems (computer output on microfilm), there are special films whose spectral sensitivity matches the light emitted by the phosphors in the cathode-ray tube screen.

Certain types of microfilm can be developed by simple heating, without any chemical treatment. Duplicates are often made on inexpensive diazo or vesicular films (→ Imaging Technology, Chap. 2.3.).

Under proper storage and processing conditions, developed microfilms have an indefinite lifetime.

Packaging. 16, 35, 70, and 105 mm, commonly unperforated; 16 and 35 mm perforated; in lengths of 30, 60, 120, and 300 mm, and in sheet form.

8.2.5. Radiographic Materials [471], [482–486]

Radiographic images are principally shadow images created by the direct transmission of X-rays through the object. The image on the screen or on the developed film represents variations in X-ray absorption over the object. The local absorption is determined by intrinsic properties of the material (atomic number), the composition, and the thickness. Usually the radiograph is a negative image that can be viewed and interpreted in transmitted light. X-ray films are often coated on both sides of a dimensionally stable polyester base (colored or uncolored). Radiography requires high contrast in order to enhance details. Radiographic materials can be broadly divided into two classes: screen films and nonscreen films.

Screen Films. Screen films are preferentially used in medical diagnosis. During exposure, the film is sandwiched between two intensifying screens in a light-tight cassette, resulting in a signficant reduction of the radiation dose. An *intensifying screen* consists of a thin layer of phosphor crystals dispersed in a binder and coated on, for example, a polyester base. During exposure, the screen converts X-rays to visible light (blue, green), or UV. The output intensity of the screen is directly proportional to the intensity of the incident radiation. About 95 % of the

exposure of the film stems from the light emitted by the phosphor. Matching the spectral response of the emulsion to the color of this light results in optimal screen – film combinations.

Until 1975, blue-emitting calcium tungsten oxide [*12789-67-2*], with a conversion efficiency of about 5 %, was the main phosphor. Modern screens, having a quantum efficiency more than three times as high, are based on rare-earth compositions. The position of the peak spectral lines of these screens can be varied with dopants (activators). Current screens emit blue, green, and UV; they are manufactured for a variety of purposes, such as high resolution, fast or low dose. This diversity is also reflected in the selection of film materials. Orthochrome (green) and monochrome (blue) systems are common.

Double coating and relatively low silver content in the emulsion ($\leq 8\ g/m^2$) favor rapid automatic processing. A dry radiograph can be obtained within 90 s after insertion, and even shorter processing times can be expected.

The disadvantage of screen radiographs is a certain loss of image quality. The images are less sharp than direct X-ray images because of optical effects, and the image becomes mottled because of statistical fluctuations in the number of quanta incident on a given area of the screen.

The image on an intensifying screen or that displayed by a cathode-ray tube can also be photographed with a camera. The film used is a single- coated small-format sheet or roll film with a spectral response corresponding to the emission. This method is useful for routine examinations.

Nonscreen X-Ray Films. Direct nonscreen X-ray film is employed when fine details have to be observed (e.g., bone structure). The absorption of the emulsion layers is increased by coating with more silver and keeping the silver – gelatin ratio as high as possible. Such films are usually double- coated.

The *nondestructive testing* of materials may involve industrial radiography (→ Nondestructive Testing , Chap. 2.2.). The inspection of steel castings and pipeline joints is a well-known application. The detection of small defects requires high-resolution direct X-ray materials without phosphor screens. The films may, however, be provided with intensifying lead foil and placed in a heavy-duty packaging for use under difficult conditions, for example, in machine shops or outdoors. The lead screen acts as a source of secondary electrons and also reduces X-ray scattering. The range of X-ray energies employed is much broader than in medical applications, because of the great diversity of materials to be tested. The film must show a fairly constant response over a wide energy range, including high-energy radiation from radioisotopes. The films are double- coated and contain up to 25 g silver per square meter. Low-speed materials with very high resolution are also available.

8.2.6. Infrared Films and Plates [466], [487–489]

Infrared films have special dyes providing sensitivity up to 1300 nm, but more commonly to 900 – 1000 nm. Both B & W and color materials are available. The color film, a "false color" material, consists of three emulsion layers sensitized in the green (nearest the base), red, and infrared (top layer); after processing, however, these form yellow, magenta, and cyan images (in the same order). The image shows no natural colors but reveals details that differ in reemission quality.

Both color and B & W materials are used to penetrate haze in air and land surveys; for special applications such as agriculture, archeology, geology, and oceanography; for special effects such as "nighttime photography in daylight"; and for making multispectral images with which properties of an object can be better interpreted. Filters are almost always used during exposure in order to block the UV or visible part of the spectrum. For this reason, the practical sensitivity of these films depends strongly on the filters employed.

8.2.7. Films for Aerial Photography [490–492]

Both B & W and color materials, most of them with dimensionally stable polyester bases, are available for aerial photography.

Black-and-white aerial survey films are panchromatic films with uniform sensitization

to ca. 700 nm. To reduce scattering by haze, they are exposed behind yellow or orange filters.

The speed is comparable with camera-sensitive materials for pictorial photography. The contrast of the scene is generally lower than in the case of terrestrial photogaphy and tends to be decreased further when photographed from a higher altitude. The gamma may be varied from 0.8 to 2.0 by the developing time depending on the altitude. IR-sensitive black-and-white film is also available for specialized applications (see Section 8.2.6). *Color films* are preferentially used at low altitude because the low contrast at high altitude disturbs the effect of color. Materials are available as reversal films, negative films and infrared sensitive color films (false-color film see Section 8.2.6).

Reversal and negative films are structured essentially like ordinary amateur materials but with steeper gradation.

Aerial survey films are used, for example, in cartography, land use planning, oceanography, environmental monitoring, and military undertakings.

8.3. Photographic Papers

8.3.1. Papers for Continuous-Tone Reproduction

Demand for silver halide photographic papers used in professional and amateur photography has risen steadily over the years. Most of the growth is in color negative paper, with a growth rate of ca. 8 % per year. Black-and-white papers have been declining for years (stagnant at present), and color reversal paper is insignificant, with ca. 2 % of total color paper demand. In 1987 the three largest markets, Japan, Europe, and the United States, consumed ca. 500×10^6 m^2 of color negative paper, 60×10^6 m^2 of B & W paper, and 13×10^6 m^2 of color reversal paper. Nearly 50 % of color negative and B & W paper consumption is in the United States, ca. 30 % in Europe, and roughly 20 % in Japan.

8.3.1.1. Black-and-White Papers

Since a wide selection of B & W papers is available, specialists and amateur photographers are able to find the right paper for any practical application. The following different product qualities exist

1) Papers with cold, neutral-gray, or warm image tone
2) Papers with fixed or variable gradation (contrast)
3) Papers with panchromatic sensitization
4) Papers with resin-coated or baryta-coated bases
5) Papers with glossy, matt, or textured surfaces
6) Papers with or without incorporated developing agents

All B & W papers have the coating structure shown in Figure 89 in common. Emulsions vary widely and are optimized by application. Low-speed (ISO P 50) silver chloride emulsions are common for contact printing; for enlargement, emulsions with speeds between ISO P 100 and ISO P 500 (under ISO 6846-1983) are used (see Section 6.1.4).

Figure 89. Layer structure of a B & W paper (schematic) Thickness of emulsion layer plus protective layer, 8 – 10 µm. Base thickness: ca. 220 µm (RC paper plus antistatic coating), ca. 145 µm (baryta-coated paper), or ca. 245 µm (baryta-coated paperboard)
a) Protective layer; b) Emulsion layer; c) Base

Pure silver chloride and silver bromide emulsions developed in Phenidone – hydroquinone developers give neutral-gray silver deposits. Image silver shifted more toward brown (warm-black to warm-brown image tones) is obtained with silver chloride bromide emulsions. The silver coating weight of B & W papers ranges between 1.0 and 1.8 g silver per square meter depending on the emulsion type and the desired gradation.

It is often useful to examine the image during the development process. For this purpose, the perceptible differences in continuous tone reproduction and shadow definition seen under darkroom illumination (safelight) must correspond as exactly as possible to the impression given in daylight or bright tungsten light. This requirement is satisfied by yellow-green light, which has its mean wavelength at the maximum sensitivity of the eye. Such illumination is produced, for example, with tungsten light combined with an Agfa – Gevaert no. G 7 filter (Fig. 90). B & W papers should be as insensitive as possible to this safelight; i.e., they should have a sensitivity gap in the maximum-transmission range of such filters.

Figure 90. Transmission spectrum of Agfa-Gevaert no. G 7 safelight filter

Because pictorial negatives have density ranges between $D_{\text{neg}} = 0.4$ and 1.6, it is desirable (as explained in Section 6.1.5) for each type of B & W paper to vary in gradation while all the other properties remain unchanged.

The market share of *fixed-gradation B & W papers* is declining. These papers consist of up to six distinct materials, each representing just one gradation from "extra hard" ($\log ER \leq 0.5$) through "normal" ($\log ER = 0.8 - 0.9$) to "extra soft" ($\log ER = 1.35 - 1.50$, where ER denotes exposure range). Such a contrast "fan" (see Fig. 91) is obtained by modifying the emulsion composition for each gradation; in order to produce the proper $\log ER$ value (see Section 6.1.2 for definition), two or three emulsions differing in gradation and sensitivity are often mixed in the requisite proportions. If necessary, the sensitivity is controlled by the use of sensitizing dyes for the blue part of the spectrum.

Figure 91. Density curves of Brovira papers (Agfa – Gevaert) with various gradations (H in lux · s)
a) Extra soft; b) Soft; c) Special; d) Normal; e) Hard; f) Extra hard

In order to simplify stock-keeping, there have been attempts to combine in a single B & W paper the gradations required most often in practice. Papers with *optical gradation control*, in which the contrast can be varied within certain limits through precisely metered sub-toe pre-exposure (flashing), are occasionally found on the market. These make use of the fact that the density curve of an emulsion becomes flatter and flatter with increasing pre-exposure, until the pre-exposure reaches the threshold value for blackening and the emulsion becomes fogged.

The filter method, patented as early as 1911 [493], has become the standard for *variable-contrast papers* and now represents a serious threat to the market for B & W papers with fixed gradation. In this technique, first realized by Frank F. Renwick [494], the $\log ER$ is varied over the range of 0.5 – 1.3 by altering the color of the printing light, so that a single paper can be used for the entire range of gradations.

In the simplest case, the emulsion consists of a mixture of two silver chloride bromide emulsions, one of which is not sensitized and responds only to blue light, while the other is sensitized to the short-wavelength green, thus leaving the sensitivity gap as required for B & W papers

and nonetheless being sensitive to blue and green light.

If the paper is exposed through a magenta filter, which passes blue light but blocks green, both emulsions respond. A high-contrast image is produced, because the density curves add (both emulsions being blue-sensitive; see Fig. 92 A). If the paper is exposed through a yellow filter, which passes mainly green light but blocks blue, initially only the green-sensitized emulsion responds and contributes to image formation mainly in the highlights. The natural blue sensitivity of both emulsions comes into play only at higher intensities, i. e., in the shadows, thus making a low-contrast contribution to the overall image produced by the superposition of the emulsions (Fig. 92 B). The result is a flatter overall gradation.

Figure 92. Principle of a variable-contrast B & W paper
A) Blue exposure; B) Green exposurea) Unsensitized emulsion; b) Green-sensitized emulsion; c) Total gradation

Between the maximum achievable contrasts (extra hard = exposure through magenta filter; extra soft = exposure through yellow filter), any intermediate gradation can be produced by mixing color components in the exposure light. Any enlarger having a color-mixing head or filter holder with an 11-filter set can be used. Since the sensitivity of the paper depends on gradation these filters differ in gray density, so that the exposure time can be kept as constant as possible at any gradation (Fig. 93).

In addition to the standard papers with fixed gradation and the variable-gradation paper, *panchromatic B & W paper* still has a role to play. The silver halide grains in the emulsion of this paper are sensitized to red in addition to blue and green, matching the three colors of a color negative film. In this way, all the subject colors stored in the color negative film are rendered as gray values that correspond to human perception (see Section 4.1). This material is used, for example, by photojournalists who work with color negative film but wish to transmit a first report in black and white. Because of its panchromatic sensitivity, this paper can be processed only under a safelight permitted for color negative papers (e.g., Agfa – Gevaert no. 08 safelight filter).

Every user of B & W papers desires deep shadows, good highlights, and optimal whites in the finished print. Many materials have *optical brighteners* incorporated in the emulsion to enhance the whites; large amounts of optical brighteners above the emulsion may be perceived as unpleasant because of a bluish shimmer in the blacks.

Figure 93. Density curves of Multigrade paper (Ilford)
a) Filter 0 (extra soft, yellow filter alone); b) Filter 1; c) Filter 2; d) Filter 3; e) Filter 4; f) Filter 5 (extra hard, magenta filter alone)

Matt surfaces are obtained by adding starch or plastics (e.g., ethylcellulose [495] or polyvinyl compounds such as polyacrylonitrile, polystyrene, poly(methyl methacrylate) and poly(vinyl acetates) [496]) to the emulsion or protective layer before coating. In resin-coated papers (see Section 3.2.2.2), *textured surfaces* are obtained by imparting a fine pattern to the polyethylene coating on the emulsion side with a calender.

Most photographic papers, after wet processing, are dried by the application of heat. *Baryta- coated papers* are pressed between a

stretched cloth apron and a metal surface heated to 80 – 100 °C until completely dry. High-gloss surfaces are obtained by pressing the emulsion side against a highly polished stainless steel surface that is either cold or else heated to 80 – 100 °C (glazing). Papers with matting agents in the emulsion or protective layer must have the emulsion side turned toward the apron. Heat drying requires heat-resistant hardening of the emulsion layer, but above all of the protective layer. Protection against a loss of the deep blacks in glazing (burning of the blacks) is afforded by heterocycles with sulfur- containing groups, such as mercaptobenzothiazole [497]. *Resin- coated photographic papers* are moved continuously through a hot-air or infrared drying zone, where they make no contact with the heating elements, or else they are dried in air.

The following methods, singly or in combination, are used in order to obtain the photographic result more quickly.

Increase in Developing Rate. Extra-short developing times are achieved if developing agents are incorporated in the layer structure. Such papers, after exposure, are mechanically dipped into a caustic alkali – sulfite solution (activator) for a few seconds, squeezed between rubber rollers, treated with a stabilizer, and again passed through rollers. They are then subjected to a (usually automatic) mechanical heat drying. The stabilizer bath contains substances that form nonphotosensitive silver complexes. Developing machines for this activator-stabilizer system are also called "two-bath" machines. The processing time for an 18 × 24 cm paper is ca. 60 s. These papers can be held for only a short time after processing. However, they have a lifetime of a few years if they are additionally fixed and washed and if care is taken that they are not exposed for an extended time to bright light (especially sunlight), excessive heat, or high atmospheric humidity.

Shortening of Washing and Drying Times. The washing time can be cut without impairing the lifetime of paper prints only if it is impossible for chemicals of any kind, but especially thiosulfate, to penetrate into the fiber base. This can be achieved by sealing the paper base on both sides with a plastic resin (resin- coated papers). Reagents can then be removed from the thin emulsion layer by washing for 1 – 5 min; washing of conventional papers requires 10 – 30 min, depending on the thickness of the paper and the efficiency of the washing equipment.

If a combination of developing agents in the photographic layers and resin- coated paper is used, papers can be processed in very compact roller-type developing machines with activating, stabilizing, fixing, and washing baths (four-bath equipment). Such papers have a lifetime of 5 – 10 years; the processing time for an 18 × 24 cm print is ca. 60 s. Because there are a number of machines (Kodak Royal Print) using this system, especially on the U.S. market, both standard B & W papers and variable-contrast B & W papers with incorporated developers on RC bases are available. If a roller-type developing machine with the conventional sequence of baths (developing, fixing, washing) is used for these papers, archival-quality prints are obtained in ca. 4 min.

Manufacturers of black-and-white papers include: Agfa – Gevaert, Leverkusen, Germany; Argenta, Munich, Germany; Fuji, Tokyo, Japan; Ilford, London, United Kingdom; Kodak, New York, USA; Konica, Tokyo, Japan; Labaphot, Flörsheim, Germany; Mitsubishi, Tokyo, Japan; and Oriental, Tokyo, Japan.

8.3.1.2. Color Papers

All color papers use the subtractive color process so that the finished print will have whites as bright and colors as brilliant as possible (see Sections 5.1 and 5.2). *Color negative papers* require a negative film from which to print. The class of *color reversal* (*color positive*) papers includes all materials that are printed from a positive (e.g., a color reversal film or a color print). Because the coating structures and processing are largely identical, display films (used to make large color images for viewing in transmitted light) are discussed together with color negative papers. For the same reasons, overhead film is grouped with the color reversal papers.

Image formation in color papers virtually always involves the creation of yellow, magenta, and cyan dyes (*chromogenic process*, see Section 5.2.2) through exposure and development. The *silver-dye bleach process* is still important in the small color reversal paper market but only in the professional sector. This process offers outstanding color brilliance, and it formerly yielded

images with better light stability than the chromogenic processes (for a more detailed account of this material, see Section 5.4).

Color Negative Papers. Figure 94 illustrates the layer structure of color negative papers. To achieve rapid processing, all supports are resin-coated paper (see Section 3.2.2.2), which is available with a variety of surface finishes, thicknesses, and backings (normal, self-adhesive, or suitable for writing with a pen). Color negative paper on a white-pigmented polyester base has been on the market for some years; it offers not only good dimensional stability but also an extraordinarily glossy finish.

Figure 94. Layer structure of color negative paper (schematic)
Total thickness exclusive of base, ca. 10 µm. Base thickness, ca. 230 µm with ca. 170 g/m^2 paper base and ca. 30 g/m^2 polyethylene coated on either side.
a) Protective layer; b) Interlayer with UV absorber; c) Red-sensitive cyan layer; d) Green-sensitive magenta layer e) Interlayer; f) Blue-sensitive yellow layer; g) Base; h) Antistatic layer

The layers have essentially the same functions as in color negative film (see Section 5.2.2.6). The UV absorber protects the finished print against premature yellowing and color fading, but simultaneously impairs the action of the optical brighteners that are introduced during development or incorporated in the material during manufacturing. Optical brighteners beneath the UV absorber layers are less efficient while those above the color-producing layers give improved whites but cause the blacks to exhibit a bluish fluorescence.

For economic reasons, the emulsion layers are single, with a total silver coating weight of 0.6 – 0.9 g silver per square meter. The image dyes must exhibit as little secondary absorption as possible in order to prevent darkening of the colors. They should be stable for as long as possible regardless of whether the prints are stored in the dark (album) or in the light, so that the information content of the images is not lost within a few years. More than 100 years dark stability is claimed for modern color prints (see Section 6.4); a color print can hang for ca. 30 years on an interior wall not exposed to direct sunlight before it shows unacceptable color shifts [498].

The spectral sensitization of the emulsions is matched as exactly as possible to the absorption maxima of the image dyes in the color negative films; color reproduction is optimal when the sensitization curves have the least possible overlap. For the reasons discussed in Section 5.2.2.6, there is no need for a yellow filter. The granularity of color papers is not important; sharpness is enhanced by screening dyes, which are decolorized in processing. These dyes absorb scattered light during exposure, which decreases the sensitivity. There is as yet no standard for the speed of color papers; if, for example, a density of 0.6 above base plus fog is used as the sensitivity point, color negative papers have a speed of ca. ISO 5/8°.

The positions of the layers relative to the base virtually do not influence the sensitivity and sharpness of a color negative paper.

The red-sensitive cyan layer (see Fig. 94) is on top, because the dyes formed in this layer show the least light fading and the direct contact of this layer with fresh bleach-fixing bath (lowest Fe^{2+} concentration) counteracts any loss of cyan density due to leuco dye formation. The yellow layer, at the bottom of the stack, com-

pensates for some roughness of the base; the eye, which is less sensitive in this part of the spectrum, does not immediately register the density variations that result after development.

All color papers must be stored under low-temperature conditions (below 10 °C) until used.

Along with the most faithful reproduction of all colors, a crucial factor in the quality of a color paper is optimal reproduction of neutral grays without any hue. If a continuous gray wedge is exposed onto a color negative paper, the density curves for the three image dyes must virtually coincide given proper exposure and filtering (see Section 5.6). Because yellowish whites and brownish-red blacks do not suit the common tastes, the yellow density in minimum-density regions is less than the densities of the other colors, while the cyan density in high-density regions is greater than those of the other colors. This balance is established in order to avoid to a certain extent undesirable toning of white and black due to possible storage conditions (e.g., interruption in low-temperature storage) or processing effects (e.g., leuco dye formation).

For economic reasons, a given grade of color paper should give optimal results for all exposure times occurring in practice. For color negative papers, this means that optimal sensitometry must be attainable between times of 20 ms (high-capacity printer) and several minutes (large-format prints). This requirement presents a major technical challenge: The three emulsions in a color paper, which differ in speed and spectral sensitivity, must exhibit no reciprocity failure (or at least identical reciprocity failures; see Section 2.1.6) over this wide range of exposure times. If this is not the case, a type of paper must be subdivided into a short-exposure material and a long-exposure material. The latent image (see Section 2.1.4) in color papers must remain stable over a range from several seconds up to 24 h.

Color negative papers now on the market include those with *silver bromide emulsions* (> 70 % silver bromide), which are processed in 81/2 min (to the end of washing) if the chemistry corresponds to the Kodak EP-2 standard (see Section 5.3). These papers are offered in a normal version for amateur and industrial photography and a professional version with a somewhat flatter gradation (and therefore used especially for portrait work). As in the case of speed, there is no standard governing the measurement of contrast in color negative papers. If the standard for B & W paper is followed, the standard color negative paper has a log *ER* of ca. 1.0. Professional papers have log *ER* values of ca.1.2.

Silver bromide paper is increasingly being replaced by a material with*pure silver chloride emulsions* (> 98 % chloride), which is processed in just 3 min (to the end of washing) if the chemistry corresponds to the Kodak RA-4 standard (see Section 5.3). Again, a variety of gradations are available, but the material has had to be divided into short-exposure and long-exposure types.

Display Films. Display films are used for making large color images for transmission viewing. The color-producing layers have the same components as the corresponding color negative papers. These materials are therefore processed in the same baths used for papers (EP-2 or RA-4 standard). Transmission materials differ from paper prints in that they, for instance, require about twice as much dye for a brilliant image. In order to obtain optimal color reproduction, high color saturation, and deep blacks, display films must therefore be made with more than twice the coating weight of color-forming layers as color negative papers. Accordingly, they require longer processing times and large amounts of replenishers (see Section 5.3).

Figure 95 shows the coating structures of the two types of display films on the market. Figure 95 A illustrates the clear variant, which is completely transparent after processing and is intended for display cases with a matt diffuser or film. The type shown in Figure 95 B, with an opaque titanium dioxide coating, is designed for display in the case of no diffuser. The density of the TiO_2 layer is as low as possible so that a very good brightness range can be achieved, but as high as necessary so that the light is uniformly scattered and the light bulb behind the display cannot be located. The opaque layer does not, however, reflect nearly as much as a color negative paper base, so that the image in reflected light appears relatively soft.

The antihalation layer has the same purpose as in color negative films (see Section 5.2.2.6). The additional NC function of the antistatic coating is necessary because the polyester film used as base cannot adequately cope with the tensile

Figure 95. Layer structure of display films (schematic)

forces exerted by the emulsion layers and interlayers applied on top of it.
Manufacturers of color negative papers and display films include Agfa, Fuji, Kodak, Konica, Mitsubishi, and Oriental.

Color Reversal Papers. All color reversal papers described here employ the chromogenic process. Everything that has been said about bases, UV absorbers, optical brighteners, image dyes, sharpness, storage conditions, the reciprocity and latent-image behavior of the emulsions applies equally to these materials. The essential difference lies in the silver halide emulsions and in the layer structure (Fig. 96), which differs from that of color negative papers.

The emulsions used are of the silver bromide type containing a few percent of iodide; these give the strongest possible interimage effects. Interimage effects are always desirable in color prints, but whereas printing from modern color negative films can take advantage of masking (to compensate for secondary densities) and strong interimage effects (see Section 5.2.2) incorporated in the films, the originals used with color reversal papers feature no masking and only weak (color reversal film) or no (color print) interimage effects. For this reason, interimage effects in color reversal papers must make a substantial contribution to the color saturation.

In principle, the blue-sensitive and green-sensitive emulsions can employ the same sensitizing dyes used in color negative papers, but the maximum sensitivity of the red-sensitized emulsion must be at a shorter wavelength (ca. 650 nm) in order to ensure optimal spectral matching to the original. As in the case of color negative pa-

per, no standard exists for determining the speed. If the standard for color reversal film is applied, then color reversal papers have a speed of ca. ISO 12/12°.

Color reversal papers have a markedly flatter gradation than color negative papers, in accordance with the Goldberg condition (see Section 6.1.5). The exposure range is about 20 DIN (versus a maximum of 12 DIN for color negative papers), so that the blue sensitivity cannot be neglected when silver bromide emulsions are used. With regard to the layer arrangement (Fig. 96), this has the consequence that the blue-sensitive yellow layer is placed on top. As in color films the yellow filter layer that follows prevents the unwanted exposure of the greensensitive and red-sensitive layers in their intrinsic sensitivity bands.

Figure 96. Layer structure of a color reversal paper (schematic)
Total coating thickness exclusive of base, ca. 13 µm. Base thickness, ca. 240 µm with ca. 180 g/m^2 paper base and ca. 30 g/m^2 polyethylene coated on either side
a) Protective layer; b) Interlayer with UV absorber; c) Blue-sensitive yellow layer; d) Yellow filter layer; e) Green-sensitive magenta layer; f) Interlayer; g) Red-sensitive cyan layer; h)Base; i) Antistatic layer

The silver coating weight of color reversal papers is ca. 1.3 g silver per square meter, i.e., higher than that of color negative papers. The reason is that up to 30 % of the silver halide grains are developed in the first B & W developer, even without exposure, so that this fraction makes no contribution to the maximum density in the subsequent chromogenic development (see also Section 5.3).

At present, two types of color reversal papers are on the market, namely papers with normal and those with a higher contrast. Color reversal papers with normal contrast are suitable for printing from color reversal films. If, for lack of a standard, the method used for B & W papers is employed for these materials, the log *ER* value is ca. 1.9. The type with higher contrast (log *ER* around 1.7) is available for copying color prints, because the density range of prints is less than that of color reversal films.

Overhead Films. Similar to the relationship between display film and color negative paper, overhead film is a special material related to color reversal paper. Regarding the layer structure, see Figure 96 for layers above the base and Figure 95 for the base plus backings. The basic components are the same as for color reversal papers. For the same reasons cited in connection with display film the emulsion content is roughly doubled. Processing, however, is exactly the same as for color reversal papers, since the first B & W developer is active enough and the chromogenic development is already designed to go to completion.

Processing. Both color reversal papers and overhead films are currently developed with formulations corresponding to the Kodak R-3 standard (processing time 10 min to end of washing). The situation is quite different for color reversal papers working with direct positive emulsions (see Section 3.1.1). These papers can be processed in the same series of baths (see Section 5.3) used for color negative papers. This comparatively simple process is well-suited to use in an office color copier (Konica) or in a multipurpose machine (Fuji), similar to a copier, that can print from color negative and reversal films as well as positive color originals. Either a color negative paper or a color reversal paper with direct positive emulsions is employed; either type passes through the same processing system.

Manufacturers of color reversal papers and overhead films include Agfa, Fuji, Kodak, and Konica.

8.3.2. Special Applications

Papers for Coin-Operated Photo Booths. In photo booths, highly sensitive photographic papers are automatically exposed, for example by a flash tube, and automatically processed to a finished positive image. These coin-operated machines usually employ reversal development without reexposure. Papers suitable for this application have a high-speed, soft-working silver bromide emulsion, which can also be sensitized for long-wavelength light. Some brands of B & W paper for reversal development in coin-operated machines exhibit fogging when the first development is carried out to obtain the negative. In this way, the shadows show up better in the final positive image. In strongly illuminated areas, which will be white tones in the final image, undevelopable residual silver halide is left behind after the first development. This residual halide would react with sodium sulfide later, in reversal processing, forming a brown fog and thus degrading the brightest parts of the image. Undevelopable silver halide is therefore removed by the addition of sodium thiocyanate to the first developer.

After development, the material is washed briefly and the reduced silver is removed with dichromate solution acidified with sulfuric acid. After again washing and clearing in sulfite solution, the residual silver bromide still present in the emulsion is directly converted to a positive image without reexposure. This is carried out with a sulfur or selenium toning bath (usually sodium sulfide solution with sublimed sulfur or selenium dissolved in it). Another brief wash follows, and the pictures are then dried in a stream of heated air. The entire processing operation takes some 4 – 5 min.

An aim is to simplify the processing and reduce the number of steps to two, by incorporating developing agents into the emulsion and modifying the bath composition. This kind of rapid processing is effective if the paper base has a plastic resin coating on both sides, so that the chemicals in the various baths cannot penetrate into the paper.

Reversal papers for coin-operated booths are *manufactured* by Agfa – Gevaert (Reversal Waterproof), Chemco (Photomaton), and Eastman Kodak (Direktaprint).

In addition to the coin-operated B & W systems just described, there are also systems for making color photos. A positive image is obtained by the reversal, direct positive, or silver-bleach processes (see Section 5.4).

Papers for Nondestructive Testing [471]. Not only X-ray films but also X-ray papers are employed in materials testing. The latter do not reproduce details as well as films, but they are much less expensive and quite suitable for test exposures and documentation. X-ray papers are coated with a high-speed-blue-sensitive silver bromide emulsion. A blue-fluorescing intensifying screen is used with the papers, as with films (see Section 8.2.5). The emulsion is therefore only sensitized in the wavelengths where this fluorescence takes place.

In Structurix IC paper (Agfa – Gevaert), the emulsion layer, supported on a polyethylene-coated base, contains developing agents. With the help of a developing machine employing the activator-stabilizer principle (see Section 5.3.3), usable images can be obtained in 10 s.

Photographic Chart Recording Papers [466], [499]. In medicine and in technology, fast oscillatory processes must often be recorded, or a number of processes must be recorded at once in parallel. "Direct" chart recorders cannot perform these tasks either because of their inertia or because the recording devices mechanically interfere with one another. Optical recorders are used instead. Relative writing speeds of up to ca. 2200 m/s are attained (depending on the oscillograph type and light source). In general, recording papers must show relatively great blackening even after minimal exposures, but the blackening should not increase much with greater exposure, so that both rapid zero crossings and relatively slow spot movement at the extrema (amplitudes) are equally well registered. Most such papers have high-speed emulsions with steep gradation and correspondingly reduced silver content. Bases vary widely; for example, paper with a weight of ca. 90 g, with or without baryta coating, and 40 – 50 g papers with the lowest possible opacity. There is also

a wide variety of packagings with regard to roll length, width, and core diameter. Some widths are perforated on both edges. The longitudinal lines (usually spaced 2 mm apart) required for some applications are printed during packaging. So that the oscillograms can be examined as soon as possible after exposure in the recording camera, a variety of approaches to shortening the wet processing have been proposed.

A combination of a recorder and processor may be used for rapid access so that the processing automatically follows after the exposure. Some of these developing papers contain developing agents making then suitable for activation and stabilization processing.

Recording without processing is possible with special recording papers, e.g., Linagraph (Kodak) and Oscilloscript (Agfa – Gevaert). A second exposure of the paper to roomlight of relatively low intensity is sufficient to produce a visible image with a maximum density of 0.4 – 0.75 on a sligthly tinted background. Inspection can occur immediately after the paper has left the recording unit and the delay due to processing is avoided. The latent image of the trace exposure is latensified (see Section 2.1.6) i.e., photodeveloped by this second exposure. The emulsions are orthochromatically sensitized to absorb as many photons as possible from the writing beam. Halogen accepters are added in order to obtain a high print-out density and also to protect to some extent the image.

Latensified oscillograms have an unlimited lifetime if stored in a dark, dry place and protected from heat. Exposure to direct sunlight or light with a high content of UV should be minimized.

If color printing paper is employed, traces in different colors can be obtained. For every channel a specific color filter must be inserted. A disadvantage of this process is the four-step processing.

Electron-Beam Recording. Instead of recording the traces of a moving light-beam the virtually inertialess displacement of the electron-beam from a cathode ray tube (CRT) may be recorded as follows:

1) Direct exposure of the film to the electrons
2) Photographing the fluorescent trace on the screen of a CRT

Direct Exposure. This method is less common because the technique is more difficult; however, the resolution is much better. The CRT for direct exposure is not a standard type, but is provided with a film chamber and a device to transfer the sensitive material from atmospheric pressure into vacuum and back, with minimum leakage.

Direct exposure avoids the energy losses and other limitations of CRT screens. Moreover, exposure of the film in a camera in indirect exposure introduces additional losses, requiring high speed material. In contrast, even rather slow materials are suitable for direct exposure, further improving the resolution. Films and papers can be chosen from the general and technical assortment. Electron-beam recorders and electron-sensitive dry silver materials for thermal processing are supplied by 3 M.

Indirect Exposure. The more common indirect method of photographing the CRT image has many applications in addition to oscillography, e.g., in phototypesetting (→ Imaging Technology, Chap. 3.1.1.), computer output microfilm (see Section 8.2.4), radar image recording, television screen photography etc.

The intensity and spectral composition of the output radiation of the CRT determine the choice of the recording material, which must have a well-matched speed and spectral sensitivity. The recording material has high contrast and high density. For some applications the recording of traces on paper or film can be replaced by other techniques such as transient-recording and realtime digital signal processing. Nevertheless, photographic recording remains in use for prolonged monitoring and fieldwork such as surveying the railroad-system, i.e., checking the flatness of the rails. An additional advantage is the convenient measurement and comparison of a collection of different records.

A great variety of photosensitive materials (paper and film) are available, among them Polaroid instant sheet or roll film and dry silver (photothermographic) materials supplied by 3 M. The latter require only a single heat-treatment to yield an image. Materials for wet processing are mostly adapted to the conditions of rapid access by prehardening.

Papers for Line and Screened Continuous Tone Originals [500], [501], [43]. In order to

make more efficient use of the light source, these papers generally have orthochromatic sensitization and steep gradation. They can be exposed either in contact or optically, in an enlarger or a repro camera. Optimal sharpness is achieved with a vacuum back and a point light source. Paper base weights range from 100 – 140 g/m^2. Most papers are processed by the activator – stabilizer method in compact roller-transport machines.

Papers with relatively steep gradation and high speed are used for reenlargement, such as from microfilm line negatives.

Photographic materials with widths up to and beyond 1 m are used in industrial drafting offices and also for photogrammetry and topographic work. These materials are intended for machine processing. Depending on the specific application, papers can be written on or retouched with pencil or ink. They have a special backing to improve flatness under various humidity conditions. Steeply graded papers of this type are used in negative and positive contact copying of text and line originals and in the preparation (by the reflex method) of negatives from opaque originals or those printed on both sides. Since these applications sometimes involve exposure through the paper base, uniform density of the cellulose mass is subject to especially stringent requirements so that shadows will not appear in the emulsion layer.

Reflex copies are made by placing the photographic paper with its emulsion side against the original to be copied, pressing the two together, and passing light through the photo paper. The light transmitted through the photo paper is reflected from white areas of the original and largely absorbed in dark areas (print, etc.) of the original; the action of the light on the emulsion is thus stronger next to white areas. The slight differences in exposure intensity (1 : 2 arithmetic) in the emulsion can produce a marked difference in blackening in the negative only if the emulsion is particularly hard-working. Contact photographic copying papers accordingly span an exposure range of 1 : 2 – 1 : 3 (arithmetic).

Producers of an extended assortment are Agfa – Gevaert (Copyline, Rapidoprint) and Kodak (Kodaline, Kodagraph, Kodak Rapid).

Direct Positive Papers. These papers give after exposure and normal processing, without any intermediate steps, a replicate of the original as opposed to the positive images resulting from reversal processing (see Section 4.3.3.7) and diffusion transfer (see Section 4.4 and → Imaging Technology, Chap. 2.2.3.1.). However, the material must be exposed in cameras provided with a prism to obtain a correct orientation. The direct positive emulsions are often based on the solarization (see Section 2.1.6), i.e., bleaching, of prefogged grains. Otherwise, the Herschel effect (Section 2.1.6) may be applied. Suitable low-speed silver chloride emulsions containing a sensitizer [502] can be fogged with precisely metered UV light after coating on the paper and before cutting and packaging. The emulsion can also be chemically fogged before coating, e.g., with thiourea dioxide at elevated temperature and pH > 8 [503]. Yellow filters ($\lambda > 500$ nm) are used for copying by the transmission or reflex method.

Direct positive-working papers with high speed and relatively steep gradation are employed in process camera work with line originals and changes of scale. Most such emulsions are coated on polyethylene- coated bases so that processing can be done in machines. They are developed in lith developers or fast Phenidone – hydroquinone developers.

Some materials are suitable for halftone images. Manufacturers are, e.g., Agfa – Gevaert (Autoreversal Rapid, Copyline Autreversal) and Kodak (Kodagraph Autopositive, Kodaprove).

8.4. Holography and Holographic Recording Materials (→ Holograph

8.4.1. Introduction

Holography was discovered by D. Gabor [504] in 1948 – 1949. At the time, no sufficiently monochromatic light source existed, and only small objects could be represented as holograms. Holography began to advance only after the invention of the laser in 1960. Gabor himself had made "in-line" holograms, in which the virtual and real images are not separated on reconstruction (reference and object beams coaxial). Leith and Upatnieks [505] introduced the obliquely incident reference beam, thus separating the virtual and real images.

8.4.2. Principles of Holography [48–50]

According to the Huyghens – Fresnel principle, every point of an illuminated object can be regarded as the point of origin of a spherical wave, which can interfere with all other such spherical waves originating from other points of this object. This principle leads to a simple treatment of holography. Figure 97 shows an object point (c) from which a spherical wave is propagating. At the recording point, this spherical wave is superposed on a plane wave (reference wave) which is produced with a mirror (b). Since each of these waves is coherent (monochromatic), an interference pattern (hologram) is generated; this is recorded by the photographic plate (d). If this hologram (b), after processing, is illuminated with the reference wave alone (Fig. 98), the object point (c) is reconstructed by diffraction. Besides this virtual image, which is seen directly by the eye, a real image (which can be examined on a ground glass) and an undiffracted component (g) are also produced. In the language of diffraction theory, the grating generates orders − 1, 0, and +1. Since every point of a complicated object gives rise to its own diffraction grating in this way, on reconstruction a great number of points are generated, creating an image of the object in three dimensions.

Figure 97. Recording a hologram of an object point (spherical wave)
a) Laser beam; b) Mirror (reference beam); c) Object point; d) Holographic recording medium

Figure 98. Reconstruction of the hologram with an object point
a) Laser beam; b) Hologram; c) Reconstructed object point (virtual image); d) Divergent wave (primary image); e) Real object point (real image); f) Convergent wave (conjugate image); g) Undiffracted beam

A spherical wave gives rise to the Fresnel lens (Fig. 99), which is a plane object having the properties of a lens (in-line technique).

Figure 99. Fresnel zone lens
The radius of each circle is proportional to $n1/2$, where n is an integer.

The information about an object is stored in the hologram not as a real image but as a wave field. Cutting the hologram up into separate pieces therefore does not erase part of the information but gradually diminishes it because the object can then be examined only through a correspondingly smaller window.

Because the hologram embodies the wave field emitted by the object at the time of exposure, this field can be made to interfere with the wave field of the same object at a later stage. If the object has undergone some slight change in the meantime, for example through thermal expansion or warping, then the superposition field will contain interference fringes, whose number and relative positions allow quanitative de-

termination of the magnitude of the change in the object. The fact that wave fields existing at different times can be coherently superposed is of enormous importance for the use of interferometry in measurement. Special interferometric measurements are possible only with holography. The superposition of wave fields can also be accomplished by multiple exposures on a single hologram.

Two types of holograms exist: absorption and phase holograms. In *absorption holograms*, the developed density distributions carry the information. By a bleaching process, the density can be converted to a pattern of "phase structures", that is, regions differing in refractive index, which are insensitive to light as far as possible (*phase holograms*) [506]. Alternatively, the residual silver halide is used in "reversal" processes. Another possibility for production of phase holograms is to create relief structures, for example by tanning development. Finally, thick and thin holograms are distinguished. In order to obtain optically thick holograms, as much as possible of the light in the reference wave I_r for reconstruction must be diffracted into the first order I_1. The ratio $\eta = I_1/I_r$ is called the diffraction efficiency. Table 13 lists values for the most important types. With thick phase holograms, reconstruction with white light (from the sun or a sufficiently point-like source) is possible. The carrier frequency of the hologram (Bragg lattice) itself generates the needed monochromatic light. In transmission holograms, the reconstructed image appears in transmission, and for reflection holograms in reflection.

Holograms can also be copied, so that mass production is possible. An example of a mass-produced hologram is the reflection hologram in a check card or credit card, which is difficult to falsify.

8.4.3. Recording Materials [464], [507]

Because the interference pattern of a hologram in general contains structures with dimensions of the order of the wavelength of the radiation used, materials for recording must have extremely high resolving power.

In addition to photographic materials, other recording media have been proposed. Examples are thermoplastics, photopolymers, bichromated gelatin, and photoresists. Because of their high sensitivity, however, silver halide photographic materials are still preferred. Lippmann emulsions are used; i.e., photographic plates with silver halide grains having diameters substantially smaller than 0.1 µm (0.03 – 0.09 µm).

Such emulsions only have a low light-scattering action. Because of their small silver halide grains, however, the emulsions have relatively low sensitivities, so that practical holography often requires exposures lasting from some seconds to minutes. A change in position (e.g., of the object or the plate) on the order of the wavelength would completely smear out the detailed interference pattern, and so the requirements on the mechanical stability of the apparatus used for recording holograms are rather stringent.

Several firms manufacture special *materials* for holography; examples are Agfa – Gevaert, Kodak, and Ilford. The materials have glass or PETP bases. Table 14 describes materials offered by Agfa – Gevaert and Kodak. Holographic recording materials have a steep gradation, $\gamma = 5 - 8$, and extremely high resolving power.

The diffraction efficiency at high spatial frequencies is determined with diffraction optics. Figure 100 A shows schematically the process of recording two-beam interferences and the reconstruction of the hologram after processing of the photographic material.

Figure 100. Recording and reconstruction of a hologram; two beam interferences
A) Recording; B) Reconstruction
a) Photograph plate; b) Interference pattern

In recording, two plane waves with intensities I_1 and I_2 are incident on the photographic plate; the directions of incidence are symmetrical with respect to the normal. The angle between the two beams is Θ. The spatial frequency ν is then

$$\nu = \frac{2}{\lambda} \sin \frac{Q}{2}$$

Table 13. Diffraction efficiencies (%) of different types of holograms

Diffraction efficiency values	Amplitude hologram			Phase hologram		
	Thick		Thin	Thick		Thin
	T [a]	R [b]	T a.R [c]	T [a]	R [b]	T a.R [c]

Observed	3.0	3.8	4.0	95	60	33.0

[a] Transmission hologram.
[b] Reflection hologram.
[c] Transmission and reflection holograms.

Table 14. Special materials for holography [467]

Supplier	Material	Spectral sensitivity	Resolving power by diffraction, lp/mm ∗
Agfa – Gevaert	Holotest 8 E 56 HD	blue and green	5000
	Holotest 10 E 56	blue and green	3000
	Holotest 8 E 75 HD	blue and red	5000
	Holotest 10 E 75	blue and red	3000
Kodak	649 F	panchromatic	4000
	120 – 01/02	blue and red	4000
	125 – 01/02	blue and green	1600
	131 – 01/02	blue and green	1600

∗ lp/mm=line pairs per millimeter.

where λ is the wavelength of the incident light in air ($\lambda = 633$ nm for the He – Ne laser).

If $\Theta = 90°$, the spatial frequency is thus $\nu = 2235$ lp/mm (line pairs per millimeter). The spacing between two lines, found as the reciprocal of the spatial frequency, is ca. 0.45 µm.

Table 15. Relative toxicity of silver compounds in comparison to the free silver ion [509] (30-day fathead minnow embryo-larval test)

Substance	Relative toxicity
Ag^+	1 ∗
AgCl	0.003
Ag_2S	$< 0.7 \times 10^{-4}$
Ag-thiosulfate complex	$< 0.6 \times 10^{-4}$

∗ The MATC (maximum acceptable toxicant concentration) reported for the free silver ion from tests with fathead minnows was between 0.00037 and 0.00065 mg/L.

The modulation m depends on the polarization of the laser light and the ratio of the intensities I_1 and I_2. In the case shown in Figure 100, the laser light was linearly polarized with the electric vector perpendicular to the plane of incidence. The intensity ratio I_1/I_2 was taken as 0.25, so that the corresponding modulation factor was 0.8. In general, for this polarization,

$$m = \frac{2\sqrt{I_1 I_2}}{I_1 + I_2}$$

The process of reconstruction is illustrated in Figure 100 B. Beam I_2' was reconstructed with beam I_1. The intensity I_2' diffracted by the grating into the first order, and thus the ratio I_2'/I_1, depend on the angle Θ, the modulation m, and the exposure.

9. Environmental Aspects of Photographic Processing

Silver. Because *free silver ion* is highly toxic to bacteria and fish, silver is classified as an environmentally hazardous heavy metal in all countries [508]. Free silver ion occurs only in emulsion making but not in the downstream production steps, in the photographic materials, or in the processing baths. In countries where wastewater treatment is advanced, the silver present in wastewater appears as silver sulfide in the clarifier sludge.

The aquatic toxicities of the *silver thiosulfate complex* and of the extremely sparingly soluble

silver sulfide are significantly lower than that of free silver ion (see Table 15) [509], [510].

Silver releases from photographic processing are chiefly from fixing baths, but also from bleaching baths and rinse water. Fixing and bleach – fixing baths are forwarded to electrolytic silver recovery in the processing plant itself or at a recovery firm. The desilvered fixing baths can be further treated with sodium sulfide or other precipitating agents, such as trimercapto-s-triazine trisodium salt [*17766-26-6*] [511]; the residual silver and other heavy metals are recovered as sulfides. After ultrafiltration, baths treated in this way are disposed of as wastewater (after further treatments as necessary). Other treatments include:

1) Precipitation of sulfate with milk of lime
2) Reduction of COD (with H_2O_2 or ozone; see below)
3) Reduction of ammonium load by stripping of ammonia in alkaline medium

Desilvered baths and developers are often burned in hazardous-waste incineration facilities. Before shipping to the incineration plant, water can be evaporated in (vacuum) evaporators to reduce the volume. Black-and-white images that are no longer needed (e.g., X-rays) are incinerated in special furnaces; the ashes are processed by special silver recovery firms.

Regulatory limits for the release of silver into sewer systems differ widely from country to country; often they are established at the municipal level. In general, limiting levels are 0 – 3 mg silver per liter. (In some countries, regulations do not cover the release concentration but rather the silver load that can be released per square meter of material processed.)

These low silver concentrations in wash water can be achieved through

1) Low silver content in the material
2) Low silver content in the fixing bath
3) Low carryover from fixing bath into wash water (low swelling of material, good stripping equipment)
4) Treatment of wash water on ion exchangers [512]

When these practices are employed, limits of 1 – 2 mg silver per liter of wash water can currently be attained. Mixing of bath residues and overflows with rinsing water is prohibited in most countries.

Other Environmentally Relevant Bath Constituents. *Cadmium*, formerly used in warm-tone papers and special-purpose films, is no longer in use for environmental reasons. Some *developing agents* have aquatic toxicities and biodegradability is difficult (Phenidone, CD-3, CD-4) [513], [514]. It has been found, however, that no harmful effects appear at the concentrations that occur in the practice. CD-3 and CD-4 are retained in sewage plants (partly in chemically modified form) in such a way that they do not develop fish toxicity except at very high discharge concentrations [515]. *Ammonium thiosulfate* is undesirable in wastewater because of the fertilizing action of the ammonium and the high COD. Modern treatment facilities are able to eliminate this substance. Thiosulfate, like sulfate, can attack concrete sewer pipes. Release limits depend on the local circumstances (piping material, dilution in the sewer); levels < 400 mg sulfate per liter are commonly permitted.

The COD values differ sharply between photographic processing baths:

Fixing baths	40 – 100 g/L
B & W developers	10 – 150 g/L
Color developers	10 – 80 g/L
Bleaching baths	90 – 120 g/L

The COD of wash water is 500 – 3000 mg oxygen per liter. If local conditions make it necessary, aeration can be used to lower the COD of wash water by 10 – 20 %. Treatment with H_2O_2 [516] or ozone [517] is also technically feasible, but normally not used in practice.

10. Economic Aspects [518]

Table 16 shows annual sales (ex factory) of photochemical products for the Federal Republic of Germany and worldwide. The category of photochemical products includes not only films, papers, and processing chemicals for amateur and professional photographers, but also specialty products such as X-ray films, motion picture films, microfilms, sensitized graphic arts products, and printing plate materials.

Table 16. Sales (ex factory) of photochemical products

Year	Manufacturer sales, Federal Republic of Germany, 10^9 \$	Manufacturer sales worldwide, 10^9 \$
1986	1.260	19.844 *
1987	1.532	23.812 *
1988	1.703	26.273 *
1989	1.678	26.046 *
1990	2.095	29.700 *
1991	2.143 *	30.100 *

* Estimated.

The estimated breakdown in percent of the world photo market by sales regions is as follows (1990; total volume ca. \$ 75×10^9 ; includes phototechnical products such as cameras and printers):

North America	42
Western Europe	32
Other European countries	2
Japan	16
Other Far East countries	5
Other countries	3

1. Introduction

Photovoltaic cells can convert sunlight directly into electric power. The way via any thermodynamic cycle of conventional power production is avoided, the conversion process operates noiseless without any moving parts. The main components of photovoltaic cells are semiconductors (→ Semiconductors) and surface and back electrodes for collecting the current. Photovoltaic power generation is one of the most fascinating methods of providing renewable energy, and the expectations for photovoltaic cells are high.

2. The Need for Renewable Energies – History of Photovoltaics

Concerns about the finiteness of fossil fuels and the environmental problems associated with the consumption of coal, oil, and natural gas have increasingly promoted solar energy as a limitless and pollution-free energy source. However, in spite of enthusiasm and impressive research and development (R & D) results in the field of photovoltaics (PV), this technique of regenerative energy use is, more than 40 years after its discovery, still at its infancy with respect to the total power of worldwide installations and contributions to the energy demand of mankind. The reason is very simple: from the economic point of view, PV up to now cannot compete with conventional large-scale electric power production. This situation might be different if external costs of conventional power production, especially environmental damage, would be "internalized". However, discussions concerning the quantification of external costs are very controversial [1], [2], and a multinational or global agreement about enhanced installation of renewable energy systems could not yet be achieved. An essential substitution of conventional power generation by solar technologies causes enhanced energy cost, a burden that is believed to reduce the international competitiveness of a country's economy.

The history of photovoltaics is summarized in the following list:

1839	Photovoltaic effect observed at electrodes immersed in an alkaline electrolyte (A. E. Becquerel [3])
1876	Photovoltaic effect observed at selenium crystals (G. W. Adams and R. E. Day [4])
1930	Use of Cu_2O-Cu- and selenium photocells for light measurements
1954	First ″solar cell" based on crystalline silicon (c-Si) for power production; efficiency 6 % (D. M. Chapin, C. S. Fuller, G. L. Pearson [5])
1954	Solar cell made of copper-coated CdS (D. C. Reynolds et al., [6])
1954	Report about photovoltaic effect in CdS thin films (G. Nadjakov et al. [7])
1954	Terrestrial use of photovoltaics for telecommunications, military, and portable transistor radios; however, new technology not accepted by market
1956	GaAs solar cell
1956	Planning of extraterrestrial use of photovoltaics in USA (after start of "Sputnik" by the former USSR)
1958	Launching of first PV-powered satellite (Vanguard I)
1963	CdTe solar cell (D. A. Cusano [8])
1970	"Rediscovery" of photovoltaics for terrestrial use (8th International Photovoltaic Specialists Conference of the IEEE [9])
1973	Solar energy research program of the European Commission including PV at JRC, Ispra, Italy
1973	1st Oil embargo; start of larger PV R & D programs in several countries
1974	Solar cell based on monocrystalline $CuInSe_2$ (S. Wagner, J. L. Shay, P. Migliorato, M. Kasper [10])
1976	Polycrystalline – later called "semicrystalline" or "multicrystalline" – Si solar cell
1976	Amorphous silicon (a-Si) solar cell (D. E. Carlson, C. R. Wronski [11])
1978	Electronic calculator powered by c-Si solar cells
1980	Electronic calculator powered by a-Si solar cells
1980	Worldwide annual PV module production about 5 MW
1983	6.4 MW-PV power plant in USA (Carrisa Plains, CA)
1988	Efficiency of more than 30 % obtained with a GaAs – c-Si PV tandem structure
1990	Worldwide annual PV module production close to 50 MW
1996	Worldwide annual PV module production 90 MW

The year 1954 represents the beginning of the era of modern photovoltaics. Various kinds of photovoltaic cells have been developed and conversion efficiencies have been improved continuously to the present maximum levels given below, as confirmed by the standard measurement laboratories – National Renewable Energy Laboratory (NREL), Golden, CO, USA; Fraunhofer-Institut für Solare Energiesysteme (FhG-ISE), Freiburg, Germany; Sandia, USA; and the Japanese Quality Assurance Organization (JQA) [12]:

Single-crystalline Si cells	24 %
a-Si cells (not stabilized)	12.7 %
$CuInSe_2$-based cells	17.7 %
CdTe-based cells	15.8 %
Si concentrator cells (96 suns∗)	26.8 %
GaAs one sun∗ cells	25.3 %
GaAs/GaSb tandem concentrator cells (100 suns∗)	32.6 %

∗1 sun corresponds to the intensity of ordinary sunlight, 1 sun = 100 mW/cm^2.

3. Fundamentals

3.1. Features of Photovoltaic Cells

Photovoltaic cells differ from other power-generation methods by the following advantages:

1) Solar energy is limitless (approximately 75×10 GW of sunlight reaches the Earth's surface)
2) Photovoltaic energy is clean, noiseless, and does not require any moving parts. In principle it can be considered to be maintenance-free
3) Photovoltaic cells generate power with constant efficiency on a large or small scale (modularity: i.e, the same solar cell materials and structures are used, independent of system size) which contrasts with the efficiency of water and steam power generation systems which depends on the scale of the system
4) The irradiance threshold for start of output operation is very low, practically no energy inventory is needed within a PV system for operation
5) Photovoltaic cells can generate power at the place where it is to be used
6) Even diffuse light can be used to generate power (e.g., fluorescent and other indoor lighting)

However, the following disadvantages must also be considered:

1) The incident energy on a photovoltaic cell is sparse
2) There is no direct power storage function (power can only be generated under sunlight and cannot be stored in the dark.

3) Power output depends on weather conditions and incident light. Consequently, the reliability of power generation by PV power plants generally is not very high. This holds especially for Central European and other moderate climatic regions. In addition, in those regions the daily and seasonal variations of energy demand and power delivery by PV are out of phase. That means, the capacity factor and the capacity value of PV power plants are low. Thus, according to standard economical calculations, the value of PV power supplied to the public grid is low.

3.2. Principle of the Photovoltaic Effect and Characteristics of Photovoltaic Cells (→ Semiconductors, Chap. 3.)

In principle the photovoltaic effect is based on the transfer of the energy of light quanta (photons) to the electronic subsystem of a semiconductor (*internal photoeffect* → Photoelectricity, Chap. 3.), and the "collection" of this energy within a short time – before it is transferred to the atomic lattice, i.e,. converted into heat. For this energy collection an internal field in the semiconductor is required. Suitable devices are *p-n* homojunctions, *p-n* heterojunctions, *p-i-n* junctions, Schottky barriers, and metal – insulator – semiconductor junctions (MIS junctions). For introduction into basic semiconductor physics and *p-n* junction theory see, e.g., [13–15]. Figure 1 A shows a schematic diagram of a photovoltaic cell with a *p-n* junction. Since conversion of solar energy requires larger areas of the converters, a solar cell in principle must be a large-area diode with the *p-n* junction parallel to the radiation-exposed surface.

The energy band diagram of such a structure is shown in Figure 1 B. At the interface between *p*- and *n*-type conduction, carrier diffusion forms a new equilibrium state, and the negative charge of the ionized acceptors at the *p*-side as well as the positive charge of the ionized donors at the n-side create an electric field in this region (*space charge region* or *depletion layer*).

The basic processes of the photovoltaic effect are indicated in Figure 1 B: Absorption of light means that the energy of a photon is transferred to one electron in the semiconductor, regularly to one located in the valence band. If the quantum energy of the photon is greater than the energy gap E_g of the semiconductor, the electron is lifted up into the conduction band and leaves one hole in the valence band. Holes can be treated like positive carriers, though in reality they are nothing more than missing electrons. In total, one electron – hole pair is generated (see process I). The equivalent process also takes place at the *n*-side of the junction and within the space charge region. Thus, the energy of the light quanta is transferred to the electrons. The energy collection occurs by charge separation: photogenerated minority carriers (electrons in *p*-type material and holes in *n*-type material) diffusing to the junction are swept across the space charge region by the internal field and contribute to the building-up of a photovoltage, i.e., a positive charge at the *p*-side and a negative charge at the *n*-side of the junction. If an external load is connected to the cell, a current flows through the load and, consequently, the device operates as a generator.

3.3. Energy Conversion and Energy Losses in Photovoltaic Cells

During conversion of energy, especially of solar radiation, two inherent loss mechanisms occur (see Fig. 1 B):

1) The absorption of photons with quantum energies $h\nu$ considerably greater than E_g – those of the blue part of the spectrum – lifts electrons up to higher energetic regions of the conduction band. The excess energy ($h\nu$ - E_g) of the photons is converted into kinetic energy of the electrons. These electrons are named "hot" electrons. Hot electrons, however, are subjected to a very fast "thermalization" process within the conduction band, i. e., the excess energy is transferred to the atomic lattice within a time interval of less than 10^{-12} s (process II in Fig. 1 B) and will, therefore, not contribute to the photovoltaic effect.
2) light quanta with $h\nu < E_g$ cannot be absorbed by the semiconductor.

Figure 1. A) Schematic structure of a photovoltaic cell based on a *p-n* junction;
B) Energy band diagram of a semiconductor *p-n* junction, processes causing the photovoltaic effect, and loss mechanisms

Furthermore, it follows from Figure 1 B that the amount of energy of an absorbed photon that can be converted into electrical energy increases with increasing band gap E_g. The theory of the photovoltaic effect also shows that the open circuit voltage of a solar cell increases with increasing E_g (see, e.g., [16]).

Consequently, with respect to the choice of semiconductor materials for solar cells the following situation results:

To obtain high photovoltages, materials with large band gaps should be chosen
To absorb as many photons as possible and to obtain high photocurrents, materials with small band gaps should be chosen

These contradictory requirements indicate that for solar energy conversion an optimum band gap exists. According to calculations carried out by various authors (see, e.g., [17], [18]), the optimum band gap is in the range of 1.3 to 1.6 eV.

The electrons and holes generated by photon absorption will not all be collected at the contacts of the photovoltaic cell. While diffusing, they may recombine with carriers of opposite charge. These loss processes (III and IV in Fig. 1 B) depend on the diffusion length L_n of the electrons in the *p*-side and on the diffusion length L_p of the holes in the *n*-side of the device. The recombination rate decreases and the diffusion length increases with decreased defect density in semiconductors, i.e., with increased material quality (→ Semiconductors, Chap. 3.3.).

Figure 2. Energy conversion and energy losses in photovoltaic cells
E_G=band gap; $h\nu$=photon energy; W_d=width of depletion layer; L_p=diffusion length of charge carrier (electrons and holes)

Figure 2 summarizes the losses occurring in the energy conversion process of photovoltaic cells. In order to further categorize the losses in solar cells, there are two main energy losses in the process, namely the optical loss and the electrical loss. The *optical loss* includes, e.g., losses due to reflection at the surface of the solar cell and absorption of light at the rear electrode. As a first approximation, the photon flux Φ which can be absorbed in the semiconductor can be expressed as follows:

$$\Phi \approx \int_0 S(E)\cdot[1-R(E)] \cdot \{1-\exp[-\alpha(E)\cdot d]\}\,\mathrm{d}E \approx \int_{E_G} S(E)\cdot[1-R(E)] \cdot \{1-\exp[-\alpha(E)\cdot d]\}\,\mathrm{d}E \quad (1)$$

where $S(E)$, $R(E)$, and $\alpha(E)$ are the energy (E) dependencies of the photon density of sunlight S, of the surface reflectance R, and of the absorption coefficient α, respectively, and d denotes the thickness of the semiconductor. Photon density is the number of incident photons per unit area per second.

Figure 3. Equivalent circuit of a photovoltaic cell

Figure 4. Current – voltage ($I-V$) relationship of photovoltaic cells

Figure 5. Solar spectral irradiance and usable energy (shaded areas) by a single solar cell (P_1) and by a 3-cell-tandem structure ($P_1 + P_2 + P_3$)

In addition to these optical losses, *electrical losses* must be considered. They are caused by recombination processes (processes III and IV in Fig. 1 B) and by series and shunt resistances in the solar cell. These are considered in the equivalent circuit of the cell (see below, Fig. 3).

3.4. Equivalent Circuit and Current – Voltage Characteristic of Solar Cells

The equivalent circuit of photovoltaic cells is shown in Figure 3 [19]. Here, I_{ph} is the photocurrent, I_{d} the diode current, I_{sh} the shunt current, and I the output current; R_{s} is the series resistance, R_{sh} the shunt resistance, V the output voltage, and V_{J} the junction voltage. Two kinds of photocurrent exist in a photovoltaic cell: diffusion current (current flow according to concentration gradients) and drift current (current flow under an electric field). The output current $I(V)$ under illumination is

$$I(V) = I_{\mathrm{ph}}(V) - I_{\mathrm{d}}(V) - I_{\mathrm{sh}}(V) \tag{2}$$

where the diode current I_{d} is defined as follows:

$$I_{\mathrm{d}}(V) = I_0 \left[\exp\left\{q\left(V + IR_{\mathrm{s}}\right)/AkT\right\} - 1\right] \tag{3}$$

where I_0 is the reverse saturation current, q the electronic charge, A the diode quality factor, k the Boltzmann's constant, and T the absolute temperature. The diode quality factor A indicates the quality of the semiconductor junction. When an ideal semiconductor junction is used, diffusion current dominates and $A = 1$; when a poor quality semiconductor junction is used, recombination current dominates and $A = 2$. In practise, both currents exist and $n = 1 - 2$.

The shunt current I_{sh} can be written as follows:

$$I_{\mathrm{sh}}(V) = \left(V + IR_{\mathrm{s}}\right)/R_{\mathrm{sh}} \tag{4}$$

Figure 4 shows an example of the current–voltage (I–V) relationship for a photovoltaic cell; I_{sc} is the short circuit current (i.e., when $V = 0$), V_{oc} the open circuit voltage (i.e., when $I = 0$), I_{op} the optimum operating current, V_{op} the optimum operating voltage, and $P_{\max}$ the maximum output power ($P_{\max} = I_{\mathrm{op}} \times V_{\mathrm{op}}$). The fill factor ($F.F.$) is determined as follows:

$$F.F. = P_{\max}/\left(I_{\mathrm{sc}} \times V_{\mathrm{oc}}\right) \tag{5}$$

The conversion efficiency η of the photovoltaic cell is

$$\eta = P_{\max}/\left(S \cdot P_{\mathrm{in}}\right) \tag{6}$$

where S is the area of the photovoltaic cell and P_{in} is the radiant power incident on the photovoltaic cell per unit area. The conversion efficiency η is the most important parameter of a photovoltaic cell.

3.5. Tandem Structures

A way to reduce the inherent losses mentioned above is to apply tandem structures. This has already been recognized and discussed by JACKSON [20] in 1955. The effect of a tandem configuration is twofold:

1) When a second solar cell with a lower band gap E_g is placed behind the first cell (which now has to have a transparent back contact), then this second cell converts light quanta which have not been absorbed by the first cell.
2) When a third cell with a higher band gap E_g is placed in front of the first cell, then the thermalization losses (process II of Fig. 1 B) are lower than in the first cell.

These effects are visualized in Figure 5: The solid line AM 0 ("air mass 0," see → Solar Technology, Chap. 1.2.) shows – in this case the extraterrestrial – solar spectral irradiance. The hatched areas indicate the maximum power that can be converted:

P_1: by a single solar cell (cell 1),
P_2: by an additional cell (cell 2) with $E_{g2} < E_{g1}$, and
P_3: by placing a third cell (cell 3) with $E_{g3} > E_{g1}$ in front of cell 1

Quantitatively, these tandem effects have been calculated by various authors (see, e.g., [21], [22]). With a three-cell tandem structure the theoretical efficiency goes up to about 50 %.

3.6. Types of Semiconductor Junctions

There are various kinds of semiconductor junctions for photovoltaic cells, the most important of which is the *p-n* junction. Two different types of *p-n* junction exist, the homojunction and the heterojunction. The *homojunction* joins *p*- and *n*-type layers of the same semiconducting material; examples are *p*-Si/*n*-Si and *p*-GaAs/*n*-GaAs junctions. *Heterojunctions* join different semiconducting materials; examples are *p*-GaAlAs/*p*-GaAs/*n*-GaAs and *n*-CdS/*p*-CdTe junctions (see Section 4.4).

p-i-n Junctions are modifications of the *p-n* junction. Here an intrinsic undoped layer is inserted between the *p*- and *n*- layers. Other kinds of photovoltaic cells are Schottky-type and MIS-type photovoltaic cells. Schottky-type cells consist of a semitransparent metal layer and an undoped or slightly doped semiconductor layer. In the MIS-type cells, a thin insulator layer is inserted between the metal and the semiconductor.

Heterojunctions join different semiconducting materials. Examples are *p*-GaAlAs/*p*-GaAs/*n*-GaAs and junctions between compounds such as chalcogenides (CdS, CdSe, CdTe,...) and chalcopyrites ($CuInSe_2$, $CuGaSe_2$, $CuInS_2$, and their quaternary and pentenary alloys). These materials generally are not amphoteric, i.e., they only show one type of conductivity, either *p* or *n*. Therefore, *p-n* and *p-i-n* structures as in case of crystalline or amorphous silicon are not feasible. Instead, heterojunctions or MIS-structures must be prepared in order to realize solar cells. This situation not necessarily is a disadvantage. Theoretically, efficiencies of heterojunction solar cells are equal to those of *p-n* homojunction cells (see, e.g., [23]). The semiconductor with the lower band gap determines the voltage of the solar cell. This semiconductor is the decisive partner in a heterojunction and is called *absorber*. Its optimum band gap is just the same as in the case of a homojunction solar cell. The wide-band gap partner is called *collector*, however, in some structures it also absorbs part of the incident radiation. Heterojunctions even have some features that are advantageous with respect to fabrication of solar cells. Three different structures of heterojunction solar cells have been applied:

Front-Wall Solar Cells. The absorber is placed to the front of the cell, it faces the sun. So, the density of photogenerated carriers is highest at the surface of the absorber. Since the carriers have to cross the whole absorber in order to be collected at the junction, the thickness of the absorber must be optimized with respect to absorption depth and diffusion length. If the absorber is too thin, a too large part of the incident radiation is not absorbed; if the absorber is too thick, a too large part of carriers generated at the surface will – due to recombination – not reach the junction. Semiconductors with high absorptivity such as direct semiconductors (see Chapter 4) are favorable in those

structures. If the band gap of the collector is only slightly wider than that of the absorber, then the thickness of the absorber can be reduced and the collector can contribute to the absorption of the incident light. The spectral sensitivity of such a structure covers the range $h\nu > E_g$ (absorber).

Back-Wall Solar Cells. In this case the collector faces the sun. Depending on the thickness and on the optical and electronic properties of the collector, it may or may not contribute to the photocurrent. If not, then the spectral sensitivity of this structure is limited to the range $E_g(\text{absorber}) < h\nu < E_g(\text{collector})$.

Window-Absorber Structure. The window-absorber structure is a special case of the back-wall solar cell. If the band gap of the collector is sufficiently wide, it operates as a "window." This structure is the optimum case of a heterojunction solar cell. The incident light is mainly absorbed in the immediate neighborhood of the *p-n* junction, so that carrier collection and charge separation operate under optimum conditions. Figure 6, showing a band diagram of a heterojunction, indicates the window-absorber-principle.

The two partners of a heterojunction must fit together with respect to lattice constant, thermal expansion coefficient, and electron affinity. Mismatch of these parameters results in the formation of so-called interface states, i.e., energy levels at the interface that are – in the energy scale – distributed across the energy band gap. They increase the probability of recombination of electrons in the conduction band with holes in the valence band. The higher the density of these interface states, the higher will be the recombination losses of photogenerated carriers and, consequently, the losses in photocurrent. In addition, mismatch of electron affinities results in a reduced photovoltage. As indicated in Figure 6, buffer layers might be necessary for compensating mismatch between window and absorber layer. The choice of an appropriate buffer layer technology is essential for high efficiencies.

4. Types of Photovoltaic Cells

Materials with band gaps in the range $1.3\,\text{eV} < E_g < 1.6\,\text{eV}$ are suited optimally for photovoltaic cells (see Section 3.3). However, crystalline silicon (c-Si) with a band gap of only 1.1 eV is the number 1 champion since the beginning of the era of photovoltaics. This is due to its availability, the advanced knowledge of its physical properties, and the know-how of material handling and device technology. The simultaneously growing electronic semiconductor industry stimulated and enforced the development of c-Si solar cells. A decisive property of semiconducting materials with respect to PV technology and cost reduction potential is the absorption coefficient of light α. In this concern *direct* and *indirect* semiconductors have to be distinguished. Direct semiconductors show α values that are about two orders of magnitude higher than those of indirect materials. Consequently, for light-absorbing devices such as solar cells, indirect semiconductors demand a thickness that is about 100 times as thick as in case of direct semiconductors. Crystalline Si is an indirect semiconductor, whereas amorphous Si as well as the most prominent chalcogenide and chalcopyrite solar cell materials are of direct character. Consequently, the realization of cost effective thin film solar cells is easily possible with direct materials. With crystalline Si very special measures are required; some promising approaches exist (see Section 4.3).

4.1. Single- and Multicrystalline Solar Cells (→ Silicon)

The production of crystalline silicon solar cells can be subdivided into three areas:

1) Preparation of high-purity silicon
2) Production of wafers, ribbons, or sheets
3) Production of solar cells (*p-n* junction, contacts, etc.)

Figure 7 shows the manufacturing process and the cell structure of "classical" single-crystalline Si solar cells.

Preparation of High-Purity Silicon. Up to now practically all crystalline Si solar cells are made from "electronic-grade" silicon (EG-Si), an ultrapure material (impurity content $< 10^{-9}$) produced by the so-called Siemens

Figure 6. Band diagram of a heterojunction with a multilayer window

Process, which is based on fractional distillation of $HSiCl_3$ (trichlorosilane), a gaseous compound fabricated from metallurgical-grade silicon (MG-Si). A pyrolytic process retransforms the ultrapure trichlorosilane into polycrystalline silicon (poly-Si), the starting material for Si crystal growth (see Fig. 7), multicrystalline Si block casting, Si ribbon pulling, etc. Worldwide a number of efforts have been undertaken for substituting the Siemens Process by simpler and lower-cost processes [25–27]. The intention was to produce low-cost "solar-grade" silicon (SoG-Si) that is still good enough for solar cells. However, the relevance of these processes has decreased in recent years, since (a) the main efforts in Si solar cell research have been directed to efficiency enhancement, and (b) as long as the material consumption of the PV industry is $< 10\,\%$ of the total electronic-grade Si-production, the photovoltaic industry can make use of low-cost "off-specification" EG-Si and of "remelts." However, these resources are becoming scarce.

Crystal Growth. Silicon single-crystalline rods of standard quality are made using the Czochralski (CZ) method. Figure 7 shows the manufacturing process. Single crystals of top quality require higher efforts, they demand for the floating zone (FZ) method.

Czochralski Method (→ Crystal Growth). Starting material is Poly-Si obtained by pyrolytic reduction of trichlorosilane. In the Czochralski process (Fig. 7), a seed crystal of silicon on a holder is dipped into a silicon melt and then pulled up very slowly by mechanical control at a rate of about 2.5 cm every three hours. The molten material starts solidifying on the seed crystal, forming a crystalline pattern identical to that of the seed crystal.

Floating Zone Method. The floating zone method (→ Crystal Growth, Chap. 6.4.) consists of six process steps:

1) A zone of a solid rod of the nutrient material poly-Si (formation from trichlorosilane) is

Figure 7. Manufacturing process and cell structure of c-Si solar cells
A) Manufacturing process of c-Si wafers; B) Manufacturing process of c-Si solar cell and the cell structure n^+ represents a highly doped layer

heated by a high-frequency power generator and a molten zone is formed
2) The molten zone is put into contact with a silicon seed crystal
3) The zone is moved away from the seed crystal
4) A single crystal with increasing diameter grows after the molten zone has moved
5) The growing crystal is supported
6) The growing crystal is separated from the nutrient material poly-Si

The floating zone method produces c-Si single crystals of the highest quality available, however, the production costs are so high, that this technology will never be a basis for mass production of Si solar cells.

Multicrystalline Ingot Production. In order to achieve cost reduction, methods to avoid the costly techniques of single crystal production were investigated. Many approaches to prepare both low-cost and high-quality materials have been attempted. The most successful technology is the casting method resulting in "multicrystalline" ingots. Conventional designations for various crystalline states are given below:

Single- or monocrystalline	grain size > 10 cm
Multicrystalline (also called "semicrystalline")	grain size 1 mm – 10 cm
Polycrystalline	grain size 1 µm – 1 mm
Microcrystalline	grain size < 1 µm
Nanocrystalline	grain size < 100 nm

In preparing multicrystalline Si ("multi-c-Si") ingots suitable for solar cell production, the following objectives must be achieved:

1) Enlargement of grain size.
2) Absence of columnar structure in the depth. Grains of multi-c-Si have a columnar structure and it is important that there is no grain boundary, since carriers would otherwise flow across the grain boundary resulting

in recombination loss due to defects in the boundary. Grain boundaries are barriers to majority carriers (i.e., electrons in the *n*-layer and holes in the *p*-layer) and are recombination centers for minority carriers (i.e., holes in the *n*-layer and electrons in the *p*-layer).

3) Passivation of grain boundaries.
4) Exclusion of impurities.

In order to solve these problems, several methods have been developed. Many methods exist for preparing multi-Si substrates [28].

Casting Method. The casting method is shown in Figure 8. A silicon ingot can be obtained by gradually cooling molten silicon in a special pot or crucible. A silicon source is melted in a furnace, then poured into a special carbon pot with a carefully controlled vertical temperature gradient. The ingot quality depends on the cooling rate and the pot shapes and material. The ingot is then carefully sliced into thin sheets or wafers with a grain size of ca. 0.5 – 1.0 cm.

Figure 8. Casting of poly-Si substrates

The concentrations of impurities such as oxygen and carbon in the ingots are $10^{16} - 10^{17}\,\mathrm{cm}^{-3}$ and $\approx 10^{17}\,\mathrm{cm}^{-3}$, respectively. The concentration of impurities increases from the top to the bottom of the ingot ($\approx 1\times 10^{18}\,\mathrm{cm}^{-3}$ at the bottom). The conversion efficiency of solar cells using multi-c-Si obtained by the casting method decreases with increasing concentration of impurities ($\leq 1\times 10^{18}\,\mathrm{cm}^{-3}$ impurities should be present).

Casting of multicrystalline blocks is somewhat cheaper than single crystal growth, however, cells based on this material exhibit lower efficiencies. Cast material is produced by Wacker (SILSO) and Bayer (Germany), Photowatt (France), Crystal Systems and Solarex (United States), and Osaka Titanium (Japan).

Figure 9. Sawing methods for ingots
A) Multiblade saw; B) Multiwire saw

Cutting. Single-crystalline rods or multicrystalline ingots are carefully sliced into wafers. The objective is to obtain as many wafers as possible from one rod and to minimize losses in the form of "kerf" or sawdust. Typical wafer thickness is 0.35 mm, kerf losses can amount to ca. 50 %. Much has been done to improve sawing techniques and speeds. Thinner sawing, multibladed circular saws, and different types of wire saws have been developed, some of which

can cut 1000 wafers simultaneously (see Fig. 9). These processes are complicated and require a large amount of energy. Therefore, the fabrication costs of c-Si solar cells are high.

Figure 10. Manufacturing process of multi-c-Si substrates: ribbon growth method

With advanced multiwire sawing techniques remarkable reductions of kerf losses have been achieved. Furthermore, thinner wafers can be produced; the PV industry is on the way to introduce a 200-µm-wafer technology. The brittleness of the wafers and the resulting handling problems are the main obstacles

Ribbon and Sheet Growth Technologies. In order to dispense with sawing techniques that always cause material losses and require a number of production steps, various types of ribbon pulling and casting and foil preparation techniques have been investigated (altogether about 20 different methods). An overview of Si ribbon and sheet developments is given in [29]. Today, the edge-defined film-fed growth (EFG), is the only process used for the industrial production of ribbon-type Si solar cells (ASE Americas, formerly Mobil Solar). The ribbon growth method is shown in Figure 10. A graphite or ceramic die, which has a thin slit through the center (slit width ca. 400 – 600 µm) is immersed in a pool of molten silicon. A silicon sheet (ribbon) can be drawn up through the slit by capillary action.

At ASE Americas, multicrystalline silicon sheets are grown in this way in the form of large octagonal tubes which are cut into wafers by laser. The time and material consuming wafer slicing and etching steps can thus be omitted. Because of the special growth conditions (oxide and carbon content, surface roughness etc.) a special optimized solar cell technology had to be developed.

Fabrication of Solar Cells. The standard process for Si solar cell production based on Si-wafers (mostly *p*-type) is the formation of a *p-n* junction by phosphorous doping, using a thermal diffusion technique from the gaseous phase. A number of alternative techniques also have been approved.

Thermal Diffusion. After the wafers have been cut, they are coated on one side, then passed through a furnace containing phosphorus vapor (or another element with five outer shell electrons, e.g., As or Sb) for just enough time to allow the phosphorus to diffuse a short distance into the silicon, converting it into a very thin layer of *n*-silicon. At the front of deepest penetration of phosphorus, a static electricity barrier is formed spontaneously and immediately.

In the thermal diffusion technique, it is difficult to implement an abrupt decrease (to zero level) of the phosphorus concentrations at the *n-p* interface, usually the phosphorus distribution follows the shape of an error function.

Alternative Technologies. More abrupt donor distributions can be obtained, e.g., by ion implantation. Other techniques result in reduced cost when they are applied in conjunction with especially cheap technologies such as screen printing of doping and contacting materials. The most important alternative techniques are:

1) Diffusion out of a solid phase previously deposited by chemical vapor deposition (CVD), spin-on, or screen printing (screen printing is successfully applied in large-scale production)

2) Diffusion out of thin solid disks, assembled as a continuous stack (batch process with high throughput)
3) Ion implantation and thermal annealing (thermal annealing also by laser/electron beam annealing)
4) Laser-induced diffusion of dopants deposited to the Si surface by evaporation, sputtering, spin-on, or spray-on
5) Direct-coupled microwave thermal processing (results in quick heating of stacked wafers)

After formation of the *p-n* junction, metal contacts are applied to each side of the cells, usually a metal plate to the bottom or *p*-side, and a grid of metallic fingers to the top or *n*-side.

Figure 11. Various cell structures of c-Si solar cells
A) BSF solar cell; B) Violet cell; C) CNR cell
a) Front electrode; b) Back electrode

Milestones of Development. Based on the cell structure shown in Figure 7 B, various structures have been developed to increase conversion efficiency.

Back Surface Field Solar Cell. Figure 11 A shows the structure of a back surface field (BSF) solar cell which was first realized in 1972 [30]. Its principle of operation was theoretically calculated even in 1963 by Martin Wolf [31]. In the BSF cell, an inner field is formed by the incorporation of a highly doped p (a p^+)-layer. The p^+-layer prevents holes and electrons from recombining near the back surface. In BSF solar cells, I_{sc} and V_{oc} increase. The increase of output power by the BSF effect is ca. 15 %, and the response of the solar spectrum for long wavelengths is improved. BSF-type solar cells are usually fabricated by preparation of highly doped layers using thermal diffusion.

Violet Cell. Figure 11 B shows a violet cell which was developed in 1972 by J. Lindmayer [32]. The n^+-layer is very thin (0.1 – 0.2 µm) compared with that of a conventional c-Si solar cell. Because of this thin n^+-layer, a *p-n* junction can be formed very close to the front surface, which prevents photogenerated carriers from recombining near the front surface of the n^+-layer. Photoresponse in the short wavelength region of the solar spectrum is improved by using this structure.

Inversion-Layer Solar Cell. Another solar cell designed to improve the response in the short wavelength region is the inversion-layer solar cell. This solar cell is fabricated by deposition of silicon dioxide on the surface of *p*-type silicon. The positive charge in SiO_2 (e.g., Na^+ adsorbed from the water used in the surface wet-cleaning process before SiO_2 deposition) is fixed near the SiO_2 – Si interface by deposition of SiO_2 on *p*-type silicon. These positively charged ions attract electrons and repel holes. As a result, a thin *n*-type inversion layer is fabricated at the c-Si surface. In the late 1980s this technology was transferred to industrial production [33]. The technology offers the economic advantage of low temperature processing, however, quenching of the fixed charges – an effect that should not occur – is the cloven hoof of the technique.

Comsat Non-Reflecting Solar Cell. Another way to improve conversion efficiency is to reduce the optical losses due to surface reflection and to increase the number of penetrating photons. Comsat non-reflective (CNR) solar cells have been developed for this purpose [34], which have many microscopic pyramids 1 – 2 µm in size at their cell surface to reduce surface reflection (Fig. 11 C). Many pyramidal structures

Figure 12. Highly efficient c-Si solar cells
A) Passivated emitter – rear locally diffused (PERL) solar cell [36]; B) Point-contact solar cell with interdigitated backside collectors [38]

with (111) planes are fabricated by the structural etching technique. The silicon wafer used for etching has a flat (100) plane which is etched using concentrated alkali to form microscopic pyramids with four (111) side planes.

Passivated Emitter Solar Cell (PESC) and Passivated Emitter – Rear Locally Diffused Cell (PERL). The idea to passivate Si surfaces and Si interfaces with thin films of SiO_2 has been introduced into PV science and technology by Martin Green, University of New South Wales (UNSW), Australia [35], [36]. It was the last real milestone on the way to highest efficiencies. Passivation reduces the losses due to surface and interface recombination of light-generated carriers in a decisive way. Even the interface between Si and the metallic contacts should be passivated; nonpassivated contact areas should at least be minimized. The PERL cell is shown in Figure 12 A. Inverted pyramid structures of the

surface of the cell allow effective light trapping. As a result, a conversion efficiency of 24.2 % at 1 sun has been reported [36]; a value of 24.0 % has been internationally accepted [12].

Point-Contact Solar Cells with Interdigitated Backside Collectors (Fig. 12 B) [37–39]. The conversion efficiency of photovoltaic cells could be significantly improved also with this novel device configuration. The structure features low metallization series resistance (low resistance in doped layers), lack of shadowing losses (no shadows caused by the electrode on the incident side surface), and lack of heavy doping effects (i.e., the heavily doped semiconductor cannot effectively generate carriers) in regions of maximum photogeneration. Furthermore, the principle of surface and interface passivation is also realized in this structure. A conversion efficiency of 28.4 % in concentrated sunlight of 79 suns has been reported [40]; a value of 26.8 % has been internationally accepted [12]. Those high efficiencies of PESC, PERL, and point-contact solar cells have been achieved with highest-quality FZ Si single crystals; they demonstrate the feasibility of efficiencies close to the maximum theoretical value (28 % at AM 1.5). For industrial production, however, FZ Si is far too expensive. Therefore, CZ-Si based efficiencies are more relevant in practice: the highest efficiency with CZ wafers (21.7 %) has been obtained at the Fraunhofer-Institute for Solar Energy Systems (FhG-ISE), Freiburg, Germany [41].

Summary of Achievements with Crystalline Silicon Solar Cells. Table 1 shows the performance of c-Si solar cells and c-Si PV modules obtained with the technologies described above.

4.2. Amorphous Silicon Solar Cells

Silicon in its amorphous hydrogenated state differs essentially in its physical properties from crystalline Si. It provides a direct optical band gap of about 1.7 eV that can be adjusted continuously from about 1.3 to 2.2 eV by forming alloys with germanium or carbon. The carrier mobility in amorphous silicon is strongly reduced as compared with crystalline Si. Effective charge collection requires implementation of a drift field in the *p-n* junction, i.e., *p-i-n* structures are required (see below).

Spear and LeComber first succeeded in the valency control (substitutional doping) of amorphous silicon (a-Si) (→ Silicon; → Semiconductors) in 1975 [42]. Production of a-Si solar cells was first reported in 1976 [43]. Since then intensive research efforts have concentrated on a-Si solar cell technology.

Figure 13. Basic fabrication method and cell structure of a-Si solar cells
A) Single chamber method; B) Basic cell structure
MFC=Mass flow controller

a-Si solar cells have many advantages that cannot be realized by other materials such as c-Si or multi-c-Si. Since the absorption coefficient of the direct semiconductor a-Si is higher than that of c-Si, even a very thin ($< 1\,\mu m$) a-Si solar cell can convert sunlight into electricity. The material costs of a-Si solar cells are therefore low. In addition, both fabrication costs and energy requirement of a-Si cells are low because of the simple and low-temperature fabrication process (see below). Large-area a-Si solar cells can be manufactured by using the plasma CVD method because the method is a gas-phase deposition. It is easy to obtain integrated-type a-Si solar cells using this fabrication process. A high

voltage can be obtained from one substrate, as will be mentioned later.

Fabrication. Figure 13 A shows a principle fabrication method for a-Si solar cells. a-Si thin films are generally prepared by a radio-frequency plasma discharge in silane (SiH_4) gas [44]. The SiH_4 molecule is decomposed in the plasma (i.e., SiH_3, SiH_2 etc. radicals are formed) and a-Si films are deposited on a suitable substrate. *p*-Type or *n*-type a-Si films can easily be obtained by adding a small amount of diborane (B_2H_6) or phosphine (PH_3), respectively, to SiH_4 gas. By changing the reaction gases (doping gases e.g., B_2H_6 and PH_3), an a-Si solar cell can be continually deposited directly onto a substrate at relatively low temperatures of 200 – 250 °C. A *p*-layer is obtained with B_2H_6 and SiH_4, an *i*-layer with SiH_4 only, and an *n*-layer with PH_3 and SiH_4.

Figure 13 B shows the basic structure of an a-Si solar cell. An a-Si solar cell is usually deposited onto a glass-transparent conductive oxide (TCO, mainly SnO_2) substrate. a-Si solar cells have a *p-i-n* junction, i.e., an undoped layer (*i* layer) is inserted between the *p* and *n* layers, while c-Si solar cells consist of a *p-n* junction. The *p*-type and *n*-type layers induce an electrical field across the entire *i* layer and photogenerated charge carriers are separated by this electric field. The typical thickness of *p*, *i*, and *n* layers are ca. 10, 500 nm, and 40 nm, respectively.

Many efforts have been made to improve the conversion efficiency and the fabrication methods of a-Si solar cells. The consecutive, separated reaction chamber method is shown in Figure 14 [45]. Here, each layer (*p*, *i*, *n*) of a-Si solar cells is fabricated in a different chamber. This method is not only effective in preventing the mutual intermixing of dopants such as boron or phosphorus, but is also suitable for mass production.

Cell structures have also been improved. a-SiC, which is usually fabricated by glow discharge in $SiH_4 - CH_4$ mixtures, has a lower absorption coefficient than a-Si. Therefore, photoresponse in the short wavelength region has been improved by using *p*-type a-SiC as a window layer for an a-Si solar cell [46] (see Figs. 14 and 15). *p*-Type a-SiC has a higher transparency than *p*-type a-Si and sunlight can pass into the intrinsic region (*i*-layer) where it is absorbed and contributes to the cells output current. A textured TCO-substrate is used in order to increase the photoresponse in the long-wavelength region.

Stability Problems. The conversion efficiency of a-Si solar cells is still lower than that of other types of solar cells. Another serious problem is the degradation of efficiency (Staebler – Wronski Effect). This can be attributed to a light-induced increase of the number of "dangling bonds" in the bulk material acting as recombination centers, which may be caused by (1) breaking of weak bond (Si-H bonds, Si-Si bonds) [47] or (2) breaking of paired bonds [48]. These mechanisms are considered to be system-inherent. Up to now, outdoor stability tests of a-Si cells and generators always resulted in a decrease of efficiency, which is not tolerable for real power applications of a-Si modules. Progress with respect to stability ap-

Figure 14. Consecutive, separated reaction chamber method

pears not to be possible by improvement of material quality; structural modifications are believed to be promising. For this purpose high drift fields are implemented, obtainable by reducing the *i*-layer thickness. The accompanying reduction of light absorption is compensated by multijunction cell structures as shown in Figure 15 D. With such structures further improvements of cell efficiencies have also been achieved due to the fact that they act like tandem structures with different band gaps. As discussed in Section 3.5, tandem structures have a potential of achieving higher efficiencies than single-junction solar cells. Initial efficiencies of 13.7 % have been obtained with a-Si-based triple junction cells. Furthermore, "stabilized" or "end of life" efficiencies of 10 to 11.83 % have been announced [49], [50]. This increase of stability is due to the higher electric fields within the *i*-layers of the triple junctions that are smaller than those of single-junction cells. The combination of a-Si and other materials such as multi-c-Si [51] and $CuInSe_2$ [52] has also been proposed (see Fig. 15 C – F).

Integrated-Type a-Si Solar Cells. An integrated-type a-Si solar cell is shown in Figure 16. Here a-Si solar cell units are arranged in cascade fashion on an insulated glass substrate [53]. This makes it possible to obtain a high voltage from one substrate. As a solar cell cannot generate voltages above 1 V, several cells are connected in series for practical use. Conventionally, series connections are made using lead wire, but unlike conventional solar cell modules, the individual cells need not be connected with a lead wire to increase voltage. This means that the structure is highly suited to various solar cell applications. During manufacturing, the TCO, the a-Si layer, and the metal electrode can be selectively patterned by a laser scribing technique [54]. A large-area a-Si solar cell module with this integrated structure can easily be obtained using a laser scribing method.

Conversion Efficiencies. Conversion efficiencies of a-Si solar cells have been greatly improved by combining many of the key technologies described above. The performance of a-Si single cells and a-Si related stacked cells are summarized in Table 2.

In recent years, the selling-prices (cost per peak Watt) of a-Si modules have been in the same range as those of crystalline Si modules. One of possible reasons is the slow deposition rate obtained with present-day industrial technologies (about 1 μm/h). The only way to overcome this problem and to increase the deposition rate by a factor of about 10, without reducing the quality of the deposited layers, at present appears to be the application of very high frequency (VHF) glow discharge techniques (very high frequency, 30 – 300 MHz). Concerning the cost reduction potential of module production, there is still optimism to bring the cost down to the range \$ 0.35 / W_p (W_p = output power, peak Watt).

mass production are a strong motivation for developing viable thin-film technologies for silicon solar cells. Nowadays, the most advanced thin-film silicon technology is that of hydrogenated amorphous Si as described above. Due to its optical properties a-Si represents a "true" thin-film solar cell material.

Further morphological modifications of silicon are also considered for thin-film solar cells, e.g., polycrystalline Si and microcrystalline Si (μc-Si) with grain sizes in the range of 1 µm and 1 to 50 nm, respectively. The decisive advantage of these modifications compared to amorphous Si is the expectation that there will be no stability problems in solar cells made from these materials. The main idea behind is to combine the advantages of crystalline Si – availability and technological know-how of the environmentally harmless material – with the economical advantages of thin-film technologies.

The design of thin-film solar cells with these materials strongly depends on their absorptivity. The absorption coefficients as a function of the quantum energy of incident light are shown in Figure 17. Polycrystalline and μc-Si have absorption curves being in between those of monocrystalline Si and of a-Si [56].

Figure 17. Absorption coefficients for different silicon-based photovoltaic materials (after [57])

Microcrystalline Silicon Thin-Film Solar Cells. Microcrystalline silicon (μc-Si, a material consisting of very small crystalline grains embedded in an amorphous Si matrix) has a relatively high absorption; layer thicknesses of 2 to 4 µm would be fully sufficient for solar cells. μc-Si has been successfully implemented in amorphous Si cells; major progress has been made using doped μc-Si for the *p*- and *n*-layers. The built-in voltage is enhanced (i.e., V_{oc} increases), the conductivity is increased, and the *n*-*p* contact

Figure 18. Cross-section of a multilayer, parallel multijunction buried contact solar cell (after [68])

in the center of a stacked multijunction structure act as a more effective tunnel junction if it is rendered microcrystalline.

A 1.7 µm thick entirely microcrystalline *p-i-n* cell deposited by VHF plasma deposition at moderate substrate temperatures (170 to 220 °C) has reached an efficiency of 4.6 % [19]. The structure resembles that of an amorphous Si cell, however, the short-circuit current is increased because of enhanced infrared absorption. Apparently, the physical properties of μc-Si depend on the volume fraction of the crystalline portion and are anywhere in between that of crystalline and that of amorphous Si. The energy gap can be as low as that of c-Si (1.1 eV), and the absorptivity approaches that of a direct semiconductor such as a-Si. The crystalline volume fraction can be controlled within a certain range by the choice of the deposition parameters. A very encouraging feature of entirely microcrystalline Si cells is that they so far do not show any degradation. With these findings, μc-Si solar cells show promising perspectives, however, the deposition rates of good-quality films are only in the range of 0.1 nm/s. They need to be increased at least by a factor of 10 in order to obtain solar cell processing times of less than one hour.

Polycrystalline Silicon Thin-Film Solar Cells. At present (in the 1990s), widespread efforts are being undertaken to realize polycrystalline Si thin-film solar cells. For summaries see [12], [56], [58]. In the case of crystalline Si thin films, the term "thin film" may be extended to film thicknesses of 20 µm or even more. Essentially it is the deposition technique that defines "thin films," for example vacuum evaporation, sputtering, chemical vapor deposition (CVD), or chemical bath deposition (CBD). Even "thick-film" techniques such as screen printing, spray-on, and spin-on may be considered. The film thickness as such is not the decisive parameter; finally, in PV it is always the price per unit of output power that counts.

The following aspects need to be considered when talking about crystalline thin-film Si solar cells:

1) Thin-film c-Si is polycrystalline with grain sizes depending on deposition technique, substrate type and temperature, and postdeposition treatments.
2) Grain boundaries cause substantial recombination losses when the flow of light-generated minority carriers has to cross them. Consequently, the grain size should be at least in the order of the film thickness, so that minority carriers can reach the *p-n* junction without crossing a grain boundary.
3) The light path in the film must be sufficiently long in order to absorb enough light to generate a short-circuit current of reasonable size (ca. 30 mA/cm^2). In case of a planar configuration the film thickness must be in the range of the absorption depth $1/\alpha$ with α being the absorption coefficient. For the major part of the solar spectrum $1/\alpha$ is in the range of 20 µm.
4) Films with a thickness of 20 µm should be deposited with high deposition rate in order to keep production time short. Furthermore, the grain size in films with planar structure should be of the order of 20 µm or more.
5) With low-cost substrates such as ordinary glass and low-cost deposition techniques such as vacuum deposition these requirements could not be fulfilled up to now [60].
6) Films of reasonable quality on amorphous substrates require substrate temperatures in

the range of 1000 °C during deposition or postdeposition annealing temperatures in the same range.

Many laboratories have published results that demonstrate the feasibility of high efficiencies even with thin-film c-Si structures. By using c-Si wafers as substrates [61–63] or by thinning c-Si wafers [64], efficiencies of more than 20 % have been achieved. Not clearly specified thin-film technologies based on "inexpensive Si feedstocks" (most probably waste of the semiconductor industry) with steel as substrates resulted in efficiencies of 9.5 % (AstroPower, [65]). With a different technology AstroPower even achieved 16.6 % [66]. However, the results of the first group can only be judged as a demonstration of the potential of thin-film c-Si solar cells. They do not have any relevance for low-cost industrial production of PV cells or modules. Furthermore, the technologies developed by AstroPower may allow a certain volume of PV business at present, but must be critically reviewed, if they depend on waste of the semiconductor industry. This previously discounted source is becoming more and more scarce. Firstly, waste is used or recycled for electronic applications, secondly, the annual increase of PV production volume results in a scarcity as such.

Figure 19. Light trapping structure with pyramidally structured glass (pyramidal film texture; after [69])
W = c-Si film (thickness = 4 µm); p = texture period = 15 µm, α = facet angle of the pyramids = 75°

Nevertheless, there are some promising approaches of producing low-cost thin-film c-Si solar cell, provided they can succeed in realizing medium or high efficiencies. Especially the texturing of the films for efficient light trapping is believed to be the key to successful developments:

- Researchers at SANYO [67] deposited an a-Si film on a textured metal substrate and crystallized it by annealing for up to 10 h at 550 – 650 °C. With a 10 µm thick polycrystalline cell a conversion efficiency of 8.5 % was obtained.
- At the University of New South Wales (UNSW) a different concept of poly-c-Si thin-film solar cells is investigated: since the problem of crystalline thin-film Si cells is the incomplete absorption of incident solar radiation, the idea was to use a stack of interlocking thin films of alternating conductivity as shown in Figure 18. The contacts to the films are metallic lines deposited into laser-eroded grooves. The left line in Figure 18 contacts all *n*-type layers, the right one all *p*-type layers. In total the arrangement between the metallic lines represents an interlocked *p-n* junction. This layered structure still provides the special advantage of thin film solar cells: the photogenerated carriers have to cover only a short distance to the next *p-n* junction, i.e., the probability of recombination on the way to the junction is low. This allows the use of thin films consisting of low-quality material like vapor-deposited polycristalline Si layers. A total thickness of 10 µm provides sufficient light absorption.
- Researchers at the Max-Planck-Institute at Stuttgart, Germany, are investigating the realization of thin-film poly-c-Si solar cells on pyramidally structured glass (see, e.g., [69]). Their light trapping studies demonstrate that Si films of only 4 µm thickness suffice to generate a maximum short-circuit current density of 35 mA/cm^2 with the "pyramidal film" texture as shown in Figure 19 having a texture period of 15 µm, a c-Si film of 4 µm thickness can generate short circuit current densities as high as 37 mA/cm^2.

4.4. Summary of the Status of Silicon Solar Cells

Figure 20 shows typical representatives of the various kinds of industrially produced silicon so-

lar cells. The standard size is still $10 \times 10\,\text{cm}^2$ for single- and multicrystalline Si cells, but larger cells are coming up for certain applications. The a-Si "cell" shown is of course a small module with a couple of cells interconnected in series.

Figure 20. Photographs of various kinds of solar cells A) Multi-c-Si (left) and single-c-Si (right) solar cell (DASA); B) a-Si solar cell (SANYO)

The c-Si solar cell is still the "working horse" in the worldwide PV scene. Its market share is about 80 % of the worldwide PV production. The rest is covered by amorphous Si and by a small quantity (less than 1 %) of CdTe-based cells. Si cells have also been referred to as "the ultimate photovoltaic solution" [70]. The availability, the technological know how, and the environmental harmlessness of the material might justify such a statement.

At present, the annual consumption of Si in the PV industry is about 1000 t. This is roughly 10 % of the total Si production for the electronic industry. So the major source of PV-feedstock Si is the material "waste" (off-specification Si, remelts, etc.). An increase in annual production of photovoltaic cells, therefore, will not necessarily result in cost decrease. The development of solar-grade Si might be unavoidable, which may go along even with increasing cost of the production technology. Consequently, thin-film technologies may be of higher topicality than presently accepted.

After an impressive start of their carrier, amorphous Si solar cells are still suffering from problems associated with limited efficiencies and with instability problems. However, in recent years higher and higher values of increased "stabilized" or "end-of-life" efficiencies have been reported, and a-Si cells and modules may now slowly enter the "power market" after having been restricted to the consumer electronics sector in the past.

4.5. Compound Semiconductor Solar Cells

Before discussing the most relevant compound semiconductor solar cells, namely the thin-film cells based on chalcogenides and chalcopyrites, the III – V (i.e., elements from group 13 and group 15 of the Periodic Table) semiconducting compounds will be treated shortly.

III – V Compound Solar Cells. Gallium arsenide (GaAs) is the most commonly used material in III – V compound solar cells. Gallium arsenide has excellent characteristics: its band gap of 1.43 eV is suitable for effectively converting solar light into electric energy. Since the band gap of GaAs is wider than that of silicon, GaAs solar cells can operate at relative high temperatures. Therefore, GaAs solar cells are suitable for use as concentrator solar cells, i.e., configurations that use lenses or mirrors to focus sunlight onto very high efficiency cells. They are also suitable for use in space because they are highly resistant to cosmic rays.

Fabrication. The surface recombination velocity (i.e., the rate of carrier recombination near the surface) of gallium arsenide solar cells is higher than that of silicon solar cells (that of GaAs is $10^6 - 10^7$ cm/s, that of Si is $\approx 10^4$ cm/s). That is why the photoresponse of *p*-GaAs/*n*-GaAs homojunction solar cells in the short wavelength range is low. In order to solve this problem, *p*-$Ga_xAl_{1-x}As$ $(0 \leq x \leq 1)$/*p*-GaAs/*n*-GaAs heterojunction solar cells have been devel-

oped. The manufacturing process and cell structure of this type of solar cells is shown in Figure 21.

Figure 21. Manufacturing process and cell structure of GaAs solar cells
LPE=liquid-phase epitaxy; MOCVD=metal organic chemical vapor deposition

In p-$Ga_xAl_{1-x}As$ $(0 \leq x \leq 1)$/p-GaAs/n-GaAs heterojunction solar cells, the band gap of the p-GaAlAs commonly used is about 2.1 eV. The GaAs band gap varies with aluminum content; if excess Al is present the band gap becomes wider, deficiency in Al narrows the band gap. Photons with energies < 2.1 eV are not absorbed in the p-$Ga_xAl_{1-x}As$ $(0 \leq x \leq 1)$ layer but in the n-GaAs layer. Therefore, photovoltaic performance is not adversely affected by the p-$Ga_xAl_{1-x}As$ $(0 \leq x \leq 1)$ surface. Conversion efficiencies of more than 25 % have been achieved by using p-$Ga_xAl_{1-x}As$ $(0 \leq x \leq 1)$/p-GaAs/n-GaAs heterojunctions (see Table 3) .

The remarkable know how available in the production technology of III – V compounds allows the epitaxial growth of multilayer structures with varying composition. With the experience in producing semiconductor laser structures and integrated optoelectronic devices it was obvious also to fabricate multilayer PV devices like tandem structures and even multiple quantum well solar cells. Efficient tandem configurations are composed, e.g., of GaAs and GaInP or GaAs and GaSb (see Table 3).

In principle, these materials – GaAs, InP, and also ternary and even multinary compounds – show excellent photovoltaic properties, however, material and processing cost are high; III – V compound solar cells can be taken into account only for space applications and, possibly, for terrestrial concentrating PV systems.

CdTe-based Thin Film Solar Cells. The development of CdTe-based solar cell has created a large variety of cell structures (altogether more than ten different types; see, e.g., [24], [71]). The most successful ones have been CdTe-cells based on heterojunction structures. With n-CdS/p-CdTe heterojunctions efficiencies of about 10 to 12 % could be achieved. However, since CdS with its band gap of 2.4 eV is not an ideal window in combination with CdTe ($E_g = 1.5$ eV), the spectral sensitivity is limited to the range $1.5\,\text{eV} < h\nu < 2.4\,\text{eV}$. A further push of efficiencies towards values around 16 % has been initiated by applying real window – absorber structures such as n-SnO_2/n-CdS/p-CdTe or n-ITO/n-CdS/p-CdTe (ITO = Indium – Tin – Oxide) with very thin CdS-layers acting solely as buffer layers. This concept is shown in Figure 22, and the resulting extension of the spectral response to quantum energies beyond 2.4 eV is indicated in Figure 23. It is remarkable that the same window configuration – transparent conducting oxide (TCO) + CdS – is also appropriate for $CuInSe_2$ cells (see below).

Figure 22. Structure of a thin-film TCO/CdS/CdTe solar cell

Table 3. Performance of III – V compound solar cells and PV tandem structures (after [12])

Type of cell	V_{oc}, V	J_{sc}, mA/cm$_2$	Fill factor	Effic., %	Area, cm$_2$	Group/ organization
One sun cells						
GaAlAs/GaAs	1.022	28.17	0.871	25.1	3.91	Kopin

Figure 23. Spectral response of various CdTe solar cells (after [72])
a) CdS/CdTe cell made by Solar Cells, Inc. (SCI): $\eta = 8.5\,\%$; b) ANTEC-cell (TCO/CdS/CdTe): $\eta = 10.5\,\%$; c) TCO/CdS/CdTe-cell made by University of South Florida (United States): $\eta = 14.2\,\%$

For the deposition of the CdTe layer a large number of methods, resulting in high efficiency cells on the one hand and for economic production on the other hand, can be applied. In addition to close-spaced sublimation (CSS) and atomic layer epitaxy (ALE), also physical vapor deposition (PVD), chemical deposition methods such as spraying, electrodeposition and metallorganic chemical vapor deposition (MOCVD), and sintering of screen-printed films have been applied successfully. In most cases CdS is deposited in a chemical bath. Recent efforts for the deposition of CdS include RF sputtering and close-spaced sublimation. In the early 1980s MATSUSHITA commercialized the screen-printing technology [73], [74]; the process sequence is shown in Figure 24.

The following points are critical for the performance of CdTe solar cells:

1) It turned out to be difficult to find suitable high-quality ohmic contacts for *p*-type CdTe. Successful approaches include (1) the deposition of a Cu-doped ZnTe layer followed by the deposition of an appropriate metal such as Ni; (2) the use of a mixture of graphite, $CuCl_2$, and HgTe which is mechanically applied to the CdTe surface, and (3) vacuum evaporation of an Au contact on a chemically treated CdTe surface which modifies the stoichiometry leaving back a Te-rich surface (see, e.g., [75], [76]).
2) Postdeposition treatments must be carried out and optimized. They influence grain growth, grain orientation, and they cause interdiffusion of CdTe and CdS leading to the formation of Cd(S,Te) at the interface. $CdCl_2$-treatments and subsequent air annealing at 400 – 500 °C promote the grain growth of as-deposited thin films. The formation of mixed alloy Cd(S,Te) at the interface is believed to shift the actual *p-n* junction into the CdTe layer and to passivate the metallurgical heterointerface (see, e.g., [77], [78]).

Since a couple of years, the highest conversion efficiencies confirmed by NREL have been

Figure 24. Manufacturing process for CdS – CdTe solar cells by the screen-printing method

those reported by the research group at the University of South Florida ($\eta = 15.8\,\%$, cell area = 1.05 cm^2; see [79]). In 1996, Golden Photon, Inc., Golden, Colorado, fabricated a 0.3205 cm^2 CdTe thin-film cell with an efficiency of 16.1 % [80]. This value has also been confirmed by NREL. Values very close to 16 % have been reported also by Matsushita Battery (15.12 %; see [81]) and by Japan Energy Corp. (16.0 %; see [82]).

At present, commercial production of CdTe solar cells with a capacity of about 1 MW/a is carried out by Matsushita Battery. CdTe-module production has also been started at Golden Photon (GPI), Solar Cells Inc. (SCI) and BP Solar. (Only recently, it has been announced that GPI closed down the module production again! [83]). Module efficiencies obtained by different commercial producers are listed in Table 4. The values presented in Table 4 indicate the maturity of CdTe-module technology and its high potential for large-scale production.

Table 4. Performance of CdTe PV modules

Group/company	Area, cm^2	Power, W	η, %
Solar Cells Inc.	6728	61	9.1∗
Golden Photon	3528	27	7.7∗
Matsushita Battery	1200	10	8.7
BP Solar	4500	37	8.4
	706	7	10.1

Values marked by ∗ have been confirmed by NREL.

Estimations within the European Union revealed that the prospective costs for CdTe module production depend on the assumed annual production volume and will be in the range of 1.0 – 1.5 ECU/W$_p$ (1 ECU = 1 European Currency Unit = \$ 1.1) for the year 2000 at an estimated annual production rate of 10 MW$_p$. A U.S. study even ends up at a production cost of only 0.28 ECU/W$_p$, provided one particular factory could be operated with a production volume of 500 W$_p$ (see, e.g., [84]).

The energy pay back time for frameless CdTe modules at an energy input of about 30 kWh/m^2, which is mainly consumed in the production of the (single) glass sheet, amounts to 1.6 months. CdTe – CdS modules operated under both external and internal accelerated tests showed stable efficiency.

Thin-Film Solar Cells Based on CuInSe$_2$ and Related Compounds. The development of CuInSe$_2$ ("CIS") solar cells dates back to the mid-1970s, to the work of S. Wagner et al. [10], who reported on production of CuInSe$_2$-based single crystalline solar cells with an efficiency of 12 %. It was mainly the high absorption coefficient of this direct-band gap material that attracted the researchers' attention: thin film devices with thicknesses $< 1\,\mu$m appeared to be feasible. The handicap of the low band gap ($E_g = 1.04$ eV) could be bypassed in the following years by applying alloys with related compounds such as CuGaSe$_2$ ($E_g = 1.7$ eV) and CuInS$_2$ ($E_g = 1.55$ eV). The possibility of designing the optical properties plus the special feature of these chalcopyrites to show a type of self-passivation of grain boundaries and surfaces led to efficiencies of more than 17 % in the mid-1990s [85], [86].

The basic structure of a Cu(In,Ga)(Se,S)$_2$ ("CIGS") PV cell is shown in Figure 25. It re-

presents a modified window – absorber heterojunction with the following features:

A molybdenum back contact is deposited by sputtering or electron-beam evaporation. Mo withstands the subsequent processing conditions of the chalcopyrite film.
The CIGS absorber film is deposited with a typical thickness of 2 µm.
Since chalcopyrites commonly are not amphoteric – they exhibit only *p*-type conduction, see below – heterojunctions must be applied.
The absorber film is coated with a thin buffer layer (CdS or Cd free materials) in a chemical bath. This improves the properties of the heterojunction.
The window layer consists of ZnO which is fabricated by RF sputtering or by a CVD process.

Figure 25. Structure of a thin-film CIGS solar cell

An idea of the complexity of this multinary material system can be obtained, e.g., from the ternary-phase field of the system Cu – In – Se, which is shown in Figure 26.

Figure 26. Ternary-phase field for Cu – In – Se (after CATALANO, [58])

A movement along the tie line connecting Cu_2Se and In_2Se_3 does not involve deviations from the normal valence of the intermediate compounds, i.e., the deviation ΔZ from the ideal "valence stoichiometry" is zero along the tie line. ΔZ is given by:

$$\Delta Z = \{2\,[\mathrm{Se}] / [(\mathrm{Cu}) + 3\,(\mathrm{In})]\} - 1$$

On the line $CuInSe_2$ and the so-called ordered vacancy compounds (OVCs) $CuIn_3Se_5$ and $CuIn_5Se_8$ are located [87], [88]. Deviations normal to the tie line, however, result in an excess or a deficiency in the number of bonding electrons. In principle, the tie line represents the pseudobinary $Cu_2Se - In_2Se_3$ phase diagram of $CuInSe_2$. Phase diagrams as elaborated by various research groups have been collected in [89]. They indicate the areas of existence of $CuInSe_2$ and of the ordered vacancy compounds. The improved knowledge of the phase diagram and the large amount of experimental work resulted in a number of findings that are important with respect to the production of efficient thin film solar cells [84], [89]:

1) The conductivity of $CuInSe_2$ ranges from low-resistivity *p*-type to high-resistivity intrinsic or *n*-type, depending on deviations from ideal stoichiometry ("intrinsic" inversion).
2) Cu-rich films – films with more than 25 at % Cu – are of *p*-type ("intrinsic doping").
3) OVCs occur on the indium-rich side of the pseudobinary phase diagram. Their conductivity appears to be intrinsic or slightly *n*-type. The surface of In-rich $CuInSe_2$ films stabilizes at a composition of $CuIn_3Se_5$, in the case of Ga compounds this composition tends to be $CuGa_5Se_8$.
4) In gallium-containing chalcopyrites the possibility of inversion of conductivity – from *p*- to *n*-type – decreases with increasing Ga content and vanishes for nearly pure $CuGaSe_2$.
5) The solubility of excess Cu in $CuInSe_2$ is very small, a larger excess Cu results in segregation of Cu_2Se.

Several processes for CIGS deposition led to devices with efficiencies exceeding 16 %:

Coevaporation/vapor deposition of the elements onto a heated substrate [85], [90]

Selenization of sputtered or evaporated Cu – In precursors in H_2Se or elemental Se atmosphere [91], [92]
Diffusion of Cu and Se into $(In,Ga)_2Se_3$ precursors [93], [94]

Table 5 summarizes the highest efficiencies of CIGS cells reported in recent years.

The success of the chalcopyrite thin-film solar cell is mainly due to:

1) The vapor – liquid – solid (VLS) growth of the chalcopyrite layer caused by the segregation of a liquid Cu_xSe phase at Cu excess. The melting point of CuSe is 513 °C. In thin films this segregation occurs mainly on the surface and in grain boundaries. A model for the growth of the chalcopyrite layer under these conditions is shown in Figure 27. Due to the very high mobility of metals in the binary chalcogenides, their transport and exchange within the films is assisted by this segregated phase and large polyhedral chalcopyrite grains are formed. This mechanism offers the possibility to achieve stoichiometric material by growing the films under an excess of copper and subsequent removal of the secondary phase, e.g., by a chemical treatment (with KCN). This implies that very accurate control of the evaporation rates is not required because the stoichiometry of the segregated solid chalcopyrite is determined by the field of existence according to the phase diagram and can be additionally adjusted by a subsequent chemical treatment. By application of this method, it was possible to grow absorber films for highest-efficiency devices [99].
2) The formation of an "intrinsic *p-n* junction" that is obtainable by adjusting the vapor beam to an indium-rich beam at the end of the coevaporation process. The unwanted Cu_xSe is thus converted into useful $CuInSe_2$ that grows epitaxially on the existing nuclei. Once Cu_xSe is consumed, the Cu-deficient vapor arriving at the surface may convert the surface to the OVC $CuIn_3Se_5$. Since the OVC shows *n*-type conductivity, a quasi *p-n* homojunction in the interior of the grains is formed [100]. This reduces interface states and interface recombination losses. To the inverted surface the heterojunction partners forming the buffer and the window layer only have to provide an electronic adaption. The remaining task of the buffer layer is to avoid a potential barrier in the conduction band that would hamper the flow of photocarriers across the junction.
3) The *self-passivation* of defects, grain boundaries and surfaces, that is typical for chalcopyrites. The diffusion length, the light absorption depth, the grain size, and the film thickness – all these parameters are roughly of the same order of magnitude. If all the imperfections mentioned above would actively behave as recombination centers, then the obtainable efficiencies of thin film solar cells based on these materials would be considerably lower than the values that have been already obtained.

Research and development activities are focused on deposition and crystallite growth processes, surface properties, the impact of impurity diffusion, novel buffer layers to replace CdS, and in particular on the establishment of the production of larger-area modules. Some production lines are under construction, however, commercially produced modules are not yet available. A sequence of fabrication steps for the manufacturing of CIS modules is illustrated in Figure 28. The deposition of the absorber is based on vacuum evaporation using an in-line evaporation process with line sources for the elements. The subsequent steps in principle resemble those of a-Si module production (see Fig. 16).

The present status of module manufacturing is summarized in Table 6.

Concerning production cost and cost development, the perspectives for $CuInSe_2$ have been considered to be very similar to those of CdTe (see above): at an annual production rate of 10 MW_p, module production cost might be in the range 1.0 – 1.5 ECU/W_p in the year 2000. In case of an annual production of 500 MW_p in a single factory, according to a U.S. study, the cost could also be as low as 0.28 ECU/W_p. The APAS Music FM study of the European Commission [109] also included cost studies: on the basis of a manufacturing facility producing 60 MW_p/a the cost of all thin-film solar cell technologies (a-Si, CdTe, $CuInSe_2$) are practically the same and are in the range 0.58 – 0.68 ECU/W_p.

Table 5. Efficiencies of CIGS laboratory cells

Material	Area, cm^2	V_{oc}, mV	η; %	Laboratory
$Cu(In,Ga)Se_2$	0.414	674	17.7	NREL [95]
$Cu(In,Ga)Se_2$	0.38	647	17.6	Uppsala Univ./ IPE [86]

Environmental Aspects of Compound Semiconductor Solar Cells. Environmental, safety and health risks associated with the production and commercial use of CdTe and CIS modules have been studied in detail by Moskowitz [106] and Alsema [107]. Environmental aspects of photovoltaic module manufacturing, especially in view of CdTe and CdS, demand a minimum of material use, high yields and safe handling, as well as recycling of wastes. Apart from accidental fires there is no hazard in operation, however, concepts and measures have to be taken for disposal and recycling of modules at the end of their lifetime. Some health hazards exist with Cd and Te compounds which lead to concentration limits in air and water. CdTe – CdS modules have failed the toxicity characteristic leaching procedure CTCLP-test slightly. It is believed, however, that reduced material quantities in the deposition processes and careful recycling could overcome this problem.

Environmental, safety, and health issues also exist for manufacturing and commercial use of CIS. Concerns which are related to the use of CdS have been overcome by the development of Cd free buffer layers leading to a comparable device performance as described above. The toxicity of H_2Se during manufacturing demands special precautions. Strategies for recycling the modules are still in a designing phase.

4.6. Other Types of Photovoltaic Cells

Besides the "classical" purely solid-state semiconductor based solar cells using the internal photoeffect directly, some exotic devices are worth mentioning. They include photovoltaic devices based on organic semiconductors and electrochemical photovoltaic cells (→ Solar Technology, Chap. 5.). Furthermore, porous silicon and fullerenes have been investigated with respect to their photovoltaic properties, and also the thermophotovoltaic effect is considered for small-scale energy conversion (see, e.g., [12]). Spectacular promises have been announced for the electrochemical photovoltaic cell – termed

Figure 29. Schematic structure (A) and mechanism (B) of the nanocrystalline electrochemical photovoltaic cell (after M. Grätzel and A. J. McEvoi, [108])

Grätzel cell after its discoverer [108] – and much money has been invested in recent years in the development of this type of photovoltaic converter in Europe. Therefore, the operation principle and some major aspects of this system will be discussed here

Nanocrystalline Electrochemical Photovoltaic Cell (Grätzel Cell). Like in a conventional solar cell, the junction between an illuminated semiconductor and an electrolyte generates a photovoltage. In the 1970s and 1980s, this concept received some attention, but it has been given up because of material instability prob-

lems caused by photocorrosion. As a general experience it could be taken from literature that only devices with large band gap semiconductors exhibited a certain stability, yet they delivered only small efficiency values.

The introduction of oxide semiconductors reduced the effect of photocorrosion, particularly for *n*-type semiconductors: here the photogenerated minority carriers (holes) act as oxidants at the interface. However, oxide semiconductors such as TiO_2 have band gaps in the range of 3 eV, i.e., they are practically insensitive to solar radiation. Therefore, as shown in Figure 29, a monolayer of an electroactive dye (the sensitizer S) is introduced to sensitize the oxide semiconductor. The dye has an optical absorption band that extends across the visible spectrum. After absorption of light quanta (process 1 in Figure 29 A) charge separation occurs by electron transfer from the photoexcited dye to the semiconductor (processes 2 and 3). The dye molecule is left as an oxidizing species. The ground state of the dye is subsequently restored by a charge transfer reaction with the redox electrolyte R (process 5). The process is completed by a reduction reaction of the counter electrode with the redox system (process 4).

Early experiments with such structures resulted in low performance compared to that of their solid-state counterparts. When practical devices were fabricated, it turned out that perfect or planar surfaces are not required. Porous and polycrystalline surfaces provide even better performance, their large effective surface area is advantageous for charge transfer. No minority-carrier recombination deteriorates this cell because these carriers are not present in the semiconductor. After injection into the semiconductor, the electrons are separated from the oxidized semiconductor dye by a potential barrier. The reverse process – electron loss from the substrate to the oxidized surface species – is inhibited by chemical mechanisms.

The suitability of porous and polycrystalline semiconductor (TiO_2) layers is the big technological advantage of the system. Very cheap techniques such as screen printing and sintering can be applied for layer deposition. On the other hand, the instability of the dye could be the greatest disadvantage. Dye development, therefore, is one of the main tasks in conjunction with this system. The original photochemical dye is the natural porphyrin chlorophyll, which can sensitize TiO_2. Ruthenium porphyrins are used as sensitizers and chemisorption of ruthenium trisbipyridyl dyes resulted in structures of good performance. Further matters of concern of the Grätzel cell are electrolyte optimization and encapsulation of the complete structure.

Figure 30. Photographs of large-area solar cell modules A) a-Si modules; B) c-Si modules; C) poly-Si modules

GRÄTZEL announced efficiencies of about 10 % [12]; at FhG-ISE Freiburg even 10.9 % has been confirmed for a small-area device [110]. Yet, efficiency measurements are more complicated than for conventional PV cells because of the time constant involved with the absorption and recombination process (see, e.g., [111]). Several research institutes and companies are currently working on the technological realization of these devices. However, new solutions have to be found for interconnecting the devices in monolithic modules. Furthermore, several is-

sues concerning encapsulation and stability have still to be addressed.

Figure 31. Crop drying tunnel with PV module for operating the ventilator; (Institut für Agrartechnik in den Tropen und Subtropen, Universität Hohenheim, Germany)

4.7. Photovoltaic Modules → Solar Technology, Chap. 4.

As described above, photovoltaic technologies have progressed remarkably. Large-area solar cell modules have been developed for power-generating systems. Figure 30 shows photographs of a-Si (Fig. 30 A), c-Si (Fig. 30 B), and poly-Si (Fig. 30 C) solar cell modules.

5. Uses

Commonly it is assumed that photovoltaic cells found their first application as power supply of space satellites. In reality, in the years following 1954 terrestrial applications were envisaged first, mainly in the consumer-electronics sector (e.g., PV-powered radios, see Chap. 2). However, PV cells were very expensive in those days. In 1958, with the launching of the first PV-powered satellite (Vanguard I) the career of photovoltaics as the standard energy source for satellites and space flight started. This monopoly still persists and provides good profits to the respective PV industry. In those early years, PV activities were practically limited to the United States, France, Germany, and to the former Soviet Union.

In the early 1970s – in fact even before the first oil crisis – the terrestrial application of photovoltaics was "reinvented" and several national programs were promoted, e.g., by the DOE in the United States, by the Commission of the European Communities (CEC) and by individual governments, especially in Europe. In 1974 also Japan joined the PV community with the creation of the Sunshine Project. For several years in the late 1980s, governmental PV funding in Germany was even higher than in the United States.

Figure 32. PV-powered buoy in the Baltic Sea near Stralsund

Space application of photovoltaics demands solar cells with high power: weight ratio, high reliability, and high resistivity to radiation. For terrestrial applications, however, the demand that had first priority was reduction of production costs. In this context, the development of thin-film solar cells became most important.

Terrestrial application of photovoltaics is usually subdivided into three main fields that are discussed in the following.

Figure 33. See-through a-Si photovoltaic cell A) for a car sunroof (Sanyo); B) Cell structure

5.1. Stand-Alone Systems

The "classical" application of PV are stand-alone systems, i.e., systems that provide electric power to facilities or applications in remote places, where no public grid is available. Prominent examples are listed in Table 7. In developing countries there is a tremendous need of such applications, but a rather huge market for stand-alone PV systems also exists in industrialized countries.

Figures 31 and 32 show examples of stand-alone PV systems.

Figure 33 A shows a photovoltaic cell for car sunroofs using see-through a-Si cell modules [12]. This resulted in a clear field of vision, self-ventilation and prevention of self-discharge of the car battery. The structure of this cell module is shown in Figure 33 B. Many microscopic holes are spaced uniformly on the active area of an integrated-type a-Si photovoltaic cell. It is also suitable for home windows. The power requirement of these stand-alone systems is of the order of tens of watts.

Stand-alone applications of photovoltaic generators are cost competitive or even much more economic than the conventional power supply methods and systems that had to be used before. Examples are repeated transport and recharging of batteries, use of diesel engines or – in case of larger systems – extension of the public electricity grid. In a number of cases PV first has enabled the application itself; e.g., the PV car sunroof (Fig. 33 A). PV systems can also help to create an infrastructure in places where there is none at all. The availability of electric power increases the value of land so much that it may compensate the cost of the PV system. In such a way building land in remote places can be developed.

Stand-alone systems commonly need a battery as a storage element. In particular cases, however, e.g., with PV-powered water pumps, the water itself can act as storage medium. Furthermore, the need for pumping and the solar irradiance are "in phase." Consequently, systems of that type can be designed without storage battery. The same holds for simple air conditioning systems, drying systems, etc.

5.2. Grid-Connected Power-Generating Systems (→ Solar Technology), Chap. 4.7.

Grid-connected PV systems are facing an economic situation completely different from that

Table 7. Main application of photovoltaics in stand-alone systems

Application scope	Application	Power range (peak Watt)
Telecommunications		10 – 7000
	– Telecommunication systems – Relay stations – TV repeaters – Transmitters – Educational TV – Mobile radio	
Water systems		400 – 6000
	– Surface water pumps / irrigation – Well pumps / irrigation and potabel water – Water treatment	
Village power supply		40 – 15000
	– Hut supply /solar home systems – Small working establishments – Streetlighting – Medical stations – Overall power supply	
Environmental systems		10 – 10000
	– Measurement stations – Cathodic corrosion protection of pipelines – Sea restoration – Sewage plants	
Traffic engineering		20 – 100000
	– Emergency calling points – Parking ticket automat – Mobile traffic lights – Buoys, warning beacons – Tunnel illumination	
Domestic supply		40 – 1000
	– Weekend houses – Detached houses – Mountain huts	
Leisure		1 – 200
	– Camping, caravans – Sailing – Car ventilation – Entertainment electronics	
Military		40 – 5000
	– Mobile power supply	

of stand-alone systems: the cost of PV energy is automatically compared to the cost of electrical energy as supplied by the grid. Up to now (in 1997), PV is nowhere in the world competitive with the public grid (see Chap. 6). That is why grid-connected PV systems always have been either experimental and demonstration projects sponsored by governments or utility companies, or they have been built in the frame of supporting programs for technology improvement and market introduction like the German “1000-PV-roofs” program and similar programs in other countries. The success of these programs, however, needed the enthusiasm of individuals, the

willingness to spend an extra money for renewable energies and for a clean environment, because in most cases the governmental funding does not cover the extra cost completely.

Figure 34. Part of the 435-kW grid-connected PV system on the new engine plant of Daimler – Benz in Stuttgart – Bad Cannstatt;
Center and left: mirror-concentrated ("V-trough") PV system with single-axis tracking;
Right, background: firmly installed PV on shed roof (photograph: Mercedes – Benz)

Figure 35. 1-MW power-generation system (Shikoku Electric Power Company)

Experimental large-scale PV systems utilizing nearly exclusively crystalline Si solar cells are being operated all over the world. Still the world's largest PV plant was the 7-MW plant at Carrisa Plains, California, dismantled in 1989. In Europe, a number of large-scale experimental PV systems have been built with the sponsorship of the Commission of the EC/EU, e.g., a 300-kW plant – meanwhile enlarged to 600 kW – for a recreation center on the island Pellworm in the North Sea. Substantial funding has been provided also by European utility companies, especially in Germany and Italy. The RWE (Rheinisch – Westfälisches Elektrizitätswerk) erected a 300-kW plant at Kobern – Gondorf and a 360-kW plant at the Lake of Neurath. In recent years the Italian ENEL built a PV plant of even 3.3 MW at Serre in Southern Italy. The largest project in Europe, a PV plant on the island of Crete initiated by the Government of Greece and by Greenpeace, is intended to finally have a power output of 50 MW. Only recently, Daimler – Benz put a 435-kW PV plant into operation. It has been installed on the roofs of the company's new engine plant in Stuttgart – Bad Cannstatt. Figure 34 shows a view of this plant.

Figure 36. Roof-mounted PV system as installed in the frame of the German 1000-PV-roofs program (photograph: RWE)

In Japan, a 1-MW power-generation system was constructed by the Shikoku Electric Power Company (see Fig. 35). The results are generating a great deal of interest because they indicate that photovoltaic cells are fully capable of system interconnection, i.e., the connection of solar-power-generation systems to the supply grids of electric power companies with electric wires. Hence, electricity can be transferred between solar-power-generation systems and electric power companies' supply grids.

If photovoltaics in industrialized countries should provide a considerable amount of electric power, then real large-scale installations and large areas are required. Therefore, decentralized installations on roofs and facades of buildings are envisaged. In principle, these areas are available without cost. The "1000-PV-roofs" program, that started in 1990 in Germany, and similar programs in other countries take advantage of this possibility. In Germany the total roof area of all buildings allow PV installations of about 50 GW [112]. Figure 36 shows a roof-

mounted PV system of the first generation. It is the typical standoff mount favored in those days. Future developments, however, should consider roof-integrated PV modules that substitute the conventional roofing material and thus follow the principle of multifunctional use. An example for this approach, realized in Japan with a-Si PV modules [113] is shown in Figure 37.

Figure 37. Model house with a roof comprised of shingle-type photovoltaic cells (SANYO)

A unique case is the incorporation of PV cells into buildings as photovoltaic facades. In contrast to PV roofs, where the substitution of PV modules for conventional roofing materials does not significantly reduce the cost, the substitution of conventional facade elements by PV modules can save a considerable amount of money, especially when luxurious facade materials such as polished granite or polished marble are considered. Such facade elements are often even more expensive than PV facades. As a consequence, in particular cases the electric power delivered by PV facades is free of cost! Of course, this does not hold for low-cost facades of industrial functional buildings. Figure 38 demonstrates the ornamental effect of PV modules integrated into a facade.

The possibilities of artistic designs of facades by integrating PV modules are large. Cell type, module shape and size, module background color around cells, semitransparent modules, modules with different types of frames (slight or sturdy; from aluminum, from stainless steel, or from plastic material) or even modules without any frame – there is an open field for creativity. It is even enlarged by the fact that cells and modules of different colors are available; only some changes in the design of the antireflection coating have to be made.

5.3. Consumer Products

Especially *a-Si thin-film modules* opened this market sector due to the flexibility in cell- and module design. The integrated manufacturing technology shown in Figure 16 allows the pro-

Figure 38. PV modules integrated into a facade in Gelsenkirchen (photograph: Pilkington Solar International)

duction of modules of the appropriate size, shape, and output voltage. In 1980, pocket calculators powered by a-Si photovoltaic cells appeared on the market for the first time, and since then a-Si photovoltaic cells have been used as power sources for various consumer products.

Some applications for consumer products are shown in Figure 39. After the commercialization of pocket calculators, watches, radios, and battery chargers have also been marketed.

Figure 39. Applications of solar cells in consumer products (SANYO)

6. Economic Aspects and Market

Figure 40 shows the world production volume of photovoltaics [114], [115]. In the past, there was a rapid increase from 1982 onward, a decline in 1985, and a continuous increase since the late 1980s with an average annual rate of 15 %. The decrease of the European share in recent years is a result of the closing of PV production in Germany. Only a short time ago plans have been announced to erect solar cell production facilities in Germany again.

Figure 41. Development of PV module prices (average values worldwide)

The development of the cost of photovoltaic modules within the last 20 years is indicated in Figure 41. The minimum in 1989 resulted from the special offers of modules during the dismantling of the Carrisa Plains plant. These special offers forced the PV industry to set selling prices below cost. But in 1990 the prices were up again, especially in Europe. This was due to the German 1000-PV-roofs-program that stimulated the market considerably. Enhanced production capacities, however, brought the prices down again

Figure 40. Worldwide shipments of the PV industry; after [114] and [115]

to the present values of \$ 4 to 5/W_p in the United States and \$ 5 to 6/W_p in Europe.

In the past, the cost reduction potential has often been estimated and cost reduction goals have been formulated, e.g., by the DOE and the Japanese Sunshine Project. These goals, coupled to proposed shipments, have always been too optimistic. Even for the late 1980s the cost goal for PV modules was set to values below \$ 1/W_p! The same figure was set again for the late 1990s; and most probably it will not be achieved either. In [114] the European Photovoltaic Industry Association (EPIA) in cooperation with the Commission of the European Communities (CEC) proposed much more realistic values: it is estimated that until 2005 the industrial cost of PV modules could be reduced to 1.8 ECU/W_p, i.e., \$ 2/W_p.

Considering the fields of application of PV, it is interesting to compare the share of these fields in the past and in recent years. Figure 42 shows that in 1983 demonstration projects financed by governments absorbed half of the PV production. In other words, during the first 30 years of the era of modern photovoltaics a substantial market could not be created despite permanent governmental funding. The application shares of 1993 (see Fig. 42) clearly indicate that the "market take-off" in the late 1980s is based on cost-effective stand-alone PV systems. Government demonstration projects as well as grid-connected PV systems only play a marginal role. However, part of the stand-alone systems indicated in Figure 42 are governmentally supported as well!

A further breakdown of PV applications is depicted in Figure 43. As indicated, the communications sector has been the major area of applications in the first half of the 1990s. A significant portion is utilized for solar home systems, defined as simple PV systems mainly for lighting purposes in developing countries; and for camping, boating and leisure applications, a typical application in industrialized countries. Grid-connected PV roof and facade systems represent the fastest growing market in Europe.

7. Future of Photovoltaic Cells

The GENESIS system (Global Energy Network Equipped with Solar cells and International Superconductor grids), discussed in [117] is based on the idea that, by the early 2000s, PV systems all over the world will be interconnected by superconductors to form a global photovoltaic power system. The GENESIS system is considered to integrate also superconductor power storage systems. This may be a scenario for the very far future; it is a fascinating vision with a touch of science fiction.

To develop a more realistic picture for the near- and medium-term future of photovoltaics, conclusions from the present situation should be drawn. A down-to-earth scenario is the "Diffusion Model" of the U.S. utility company PG&E (Pacific Gas and Electric; [118]) (see Fig. 44). The various elliptical areas or sectors represent markets or fields of applications. Today, PV is successful in the market of stand-alone services and systems for remote users. In addition, PV is currently competitive in the sector of power supply for remote communities and islands. These are still stand-alone applications. By gaining experience and increasing turnover in these fields, cost will decrease and PV will become more and more competitive in the next niche, which is the sector of grid-connected building-integrated systems, i.e., PV roofs and PV facades. Continuously increasing turnover will again reduce production cost, and the next niche will be commercially attainable. This mechanism is believed to promote PV in a natural way, based on the principles of a free market. Finally, after having gained enough experience, after having achieved the status of a large-scale industry, PV is expected to be competitive also in the field of bulk power generation.

From the history of photovoltaics and from the present situation the future of PV can be summarized as follows:

1) R & D will provide the PV industry with technologies for the production of higher-efficient and/or cheaper solar cells.
2) Progress in R & D and increased turnover will make PV systems more and more competitive in increasing fields of applications; a leap of cost reduction may occur when polycrystalline thin-film solar cells – those of crystalline silicon or those of compound semiconductors – will be transferred to industrial mass production. A drastic reduction in production cost for amorphous silicon is

Figure 42. Application shares of PV modules at different times; after VIGOTTI [116]

Figure 43. Main application segments of PV (average 1990 – 1994); after [114]

not anticipated. Amorphous Si is in industrial production since 15 years and progress will only be gradual.

3) The Third World market will continue to provide excellent prospects for PV. A rural population of more than 1×10^9 people without access to electricity represents a market potential of more than 16 GW.
4) Stand-alone PV for remote applications within Europe represents a potential market of some 150 MW. Here, it should be taken into account that within Europe money for financing PV installations is available,

Figure 44. Diffusion model of PV utility applications by PG&E [118]

whereas in developing countries the need is huge, but money is scarce!

5) PV integration into buildings is a rapidly growing market. It is not primarily based on the purpose of an economic application of PV, but on engagement for environment and sustainable development, on the desire to support renewable energies and PV industry, and also on the wish to equip a building with exceptional features. This especially holds for PV facades, which can easily be in the economic range due to the saving of conventional facade elements (see Chap. 5).
6) If PV succeeds to lower system cost to the range \$ 2.00 – 2.50/W_p, then it will be competitive with diesel engines. According to experts, the diesel power market – for water pumping and for other purposes – is in the range of "thousands of megawatts."

1. Phthalic Acid

Phthalic acid [*88-99-3*], 1,2-benzenedicarboxylic acid, has remained unimportant industrially. It is formed as a byproduct in the manufacture of phthalic anhydride.

Physical Properties. Phthalic acid, $C_8H_6O_4$, M_r 166.14, forms colorless, monoclinic crystals which melt at 191 °C (sealed tube) and are converted into phthalic anhydride with the elimination of water at 210–211 °C. Some physical properties of phthalic acid are as follows [1 – 3]:

Density (15 °C)	1.593 g/cm^3
Heat of fusion	315.3 J/g
Specific heat of solid (0–99 °C)	1.214 J g^{-1} K^{-1}
Heat of combustion	19 657.03 J/g
Heat of formation	43 714.34 J/g
Heat of solution at 25 °C	123.55 J/g
Flash point	168 °C

2. Phthalic Anhydride

Phthalic anhydride [*85-44-9*], isobenzofuran-1,3-dione, has been commercially produced continuously since 1872 when BASF developed the naphthalene oxidation process. It was the first anhydride of a dicarboxylic acid to be used commercially and is comparable in its importance to acetic acid.

The most important derivatives of phthalic anhydride are plasticizers and, to a lesser degree, polyester resins and dyes.

About 60 years after its discovery in 1836 by A. Laurent, a more effective commercial process for its production was introduced, which was based on mercury-catalyzed liquid-phase oxidation of naphthalene.

The breakthrough that led to commercial production of a quality product was the development of the gas-phase oxidation of naphthalene or *o*-xylene in an air stream with vanadium oxide as catalyst [4].

2.1. Physical Properties

Phthalic anhydride, $C_8H_4O_3$, M_r 148.12, forms colorless needles or platelets, with a monoclinic or rhombic crystalline form. Some important physical properties of phthalic anhydride are as follows [1, 5, 6]:

Density of solid (4 °C)	1.527 g/cm^3
Specific vapor density (1013 mbar)	6.61 kg/m^3
Melting point	131.6 °C
Boiling point (1013 mbar)	295.1 °C
Heat of fusion	159.1 J/g
Heat of combustion	22 160.7 J/g
Heat of formation from naphthalene	12 058 J/g
Heat of formation from *o*-xylene	8625 J/g
Heat of sublimation	601 J/g
Heat of evaporation	441.7 J/g
Flash point	152 °C
Ignition temperature	580 °C
Upper limit of flammability (1013 mbar)	10.5 vol %
Lower limit of flammability (1013 mbar)	1.7 vol %
Lower dust explosion limit	25 g/m^3

The density of liquid phthalic anhydride in the range 140–240 °C can be calculated by using the following equation [7]:

$$\varrho/\mathrm{kg\,m^{-3}} = 1321.55 - 0.6697\,(\mathrm{t}/^\circ\mathrm{C}) - 0.000905(\mathrm{t}/^\circ\mathrm{C})^2 \quad (1)$$

Table 1 lists the solubility of phthalic anhydride in various solvents.

Table 1. Solubility of phthalic anhydride

Solvent	Temperature, °C	Solubility, g/100 g
Water	20	1.64
Water	50	1.74
Water	100	19.0
Carbon disulfide	20	0.7
Formic acid	20	4.7
Pyridine	20	80
Benzene		soluble
Ethanol	20	soluble
Diethyl ether	20	slightly soluble

The reported explosion hazard data of phthalic anhydride in air vary significantly [4, 5]. Explosions can occur at concentrations below 100 g/m^3, depending on the impurities present. Recent incidents in production plants indicate that phthalic anhydride concentrations exceeding 35 g/m^3 in the reaction product gas are capable of ignition if heat-transfer salt enters the reactor due to broken reactor tubes.

2.2. Chemical Properties

As a cyclic anhydride, phthalic anhydride is a reactive compound, but in addition, the otherwise very stable aromatic ring is capable of reaction. Phthalic anhydride reactions which have

achieved commercial importance are summarized below. The most important is the reaction with alcohols or diols to give esters or polyesters.

Unsaturated polyester resins are obtained by polycondensation in the presence of maleic anhydride or fumaric acid.

One or both of the carboxy groups can react with ammonia to give phthalic monoamide and phthalimide [*85-41-6*] or phthalonitrile [*91-15-6*].

Phthalein and rhodamine dyes, some of which have been in production for over 100 years and have not yet lost their importance, are obtained by reaction of phthalic anhydride with phenols, aminophenols or quinaldine derivatives. The Friedel–Crafts reaction of phthalic anhydride with benzene derivatives followed by ring closure to form anthraquinone derivatives is of importance as a route to Indanthrene dyes.

Much attention has been devoted to the rearrangement of dipotassium phthalate to produce terephthalic acid [*100-21-0*] [8], but due to technical problems the process is no longer used.

3,5-Dihydrophthalic acid can be produced by electrochemical hydrogenation of phthalic anhydride [4]. Hydrogenation with a nickel catalyst produces phthalide [*529-20-4*].

2.3. Resources and Raw Materials

In the 1960s a fundamental shift took place in the raw material base for phthalic anhydride. From 1960 to 1975 the production was switched from 100 % coal-tar naphthalene to about 75 % *o*-xylene. In 1991, 85 % of phthalic anhydride was produced from *o*-xylene [9]. Naphthalene derived from petroleum, which is produced mainly in the United States, has not gained importance as a raw material for phthalic anhydride.

The changeover to *o*-xylene as the feedstock was inevitable because the quantities of naphthalene derived from coal tar depend on the production of coke and these were unable to keep pace with the increasing demand for naphthalene. On the other hand, naphthalene is an inevitable byproduct of coke production which should be used commercially; therefore, the phthalic anhydride process will continue to use some naphthalene as feedstock in the future. *o*-Xylene, which can readily be separated from the mixture of xylenes containing roughly one third *o*-xylene and two thirds *p*-xylene, is nowadays available in adequate quantities from cracking plants and refineries. However, in the past, variations in the demand for *p*-xylene have often affected the availability and price of *o*-xylene, as has the need to increase the amount of alkyl aromatics in unleaded gasoline.

These facts and the need to be able to react to varying raw material prices have resulted in plants being planned which are capable of processing *o*-xylene or naphthalene or mixtures of the two with tailor-made catalysts.

2.4. Production

2.4.1. Gas-Phase Oxidation

Phthalic anhydride is predominantly produced on an industrial scale by gas-phase oxidation of *o*-xylene or naphthalene.

General Features. Preheated *o*-xylene is introduced into a stream of hot air. The *o*-xylene–air mixture is passed through a tubular reactor where the exothermic oxidation takes place on a highly selective catalyst. The heat of reaction is used to produce steam, only part of which is utilized in the plant itself. Any excess steam can be used elsewhere. The gases emerging from the reactor are precooled. At high loadings of phthalic anhydride in the product gases, some liquid phthalic anhydride can be won in a liquid condenser. The product gases are then fed

to a switch condenser system where the phthalic anhydride is condensed on the finned tubes as a solid. The switch condensers are cooled by a heat-transfer oil in an automated switching cycle. During the heating cycle the deposited phthalic anhydride is melted and collected in a storage tank.

After the phthalic anhydride has been separated, the exhaust gases still contain byproducts and small quantities of phtalic anhydride and must be cleaned by scrubbing with water, or catalytically or thermally incinerated. If scrubbing with water is employed, it is possible to concentrate the main byproduct, maleic acid, and the scrubbing solution can then be processed further to yield fumaric acid or maleic anhydride [10, 11]. If the scrubbing of the exhaust gases is combined with production of maleic anhydride, the discharge of any polluted wastewater from the plant can be avoided.

The crude phthalic anhydride is transferred to a continuous thermal/chemical treatment system, which converts the phthalic acid formed as a byproduct into the anhydride. The crude product is then purified in a continuous two-stage distillation system [12].

The BASF process can be operated with a wide range of o-xylene loadings up to 105 g/m^3 (STP). The reactor outlet gases are further treated catalytically in a finishing reactor to decrease the amount of byproducts and to improve product quality. Flexible operation of the reactor system enables the phthalic anhydride yield to be optimized and decreases the amount of residues and volatile organic compounds. Simultaneously a smoother operation of the catalyst in the tubular reactor prolongs its life. Addition of SO_2 to activate the catalyst is not required, and there is no need for a liquid condenser before collecting the crude phthalic anhydride in the switch condensers. Because of the low byproduct content, chemical treatment of the crude phthalic anhydride is unnecessary. The plant design is optimized for low energy consumption and a high net export of steam and electrictity [13].

The Wacker process makes it possible to use *o*-xylene or naphthalene or mixtures of the two. With *o*-xylene, loadings of 90–100 g/m^3 (STP) are possible [14, 15]. Modifications of the process are aimed at saving energy [16].

The Nippon Shokubai VGR Process. In patent literature, the Nippon Shokubai VGR (vent gas recycling) process is described. Its characteristic feature is, that exhaust gas is recycled and added to the mixture of *o*-xylene and process air to reduce the oxygen concentration to less than 10 vol %. This makes it possible to work outside the limits of flammability despite a high *o*-xylene loading (up to 85 g/m^3 STP). Despite the low O_2 concentration, yields of up to 116 g PA/100 g xylene (given as 116 % by PA producers) have been reported. This is attributed to a specially developed catalyst system. It is also possible to use naphthalene instead of *o*-xylene in this process [17 – 21].

The Alusuisse–Ftalital LAR Process. In the LAR (low air ratio) process, *o*-xylene loadings in the process air of up to 134 g/m^3 (STP) are suggested. This could make it possible to achieve an appreciable reduction in energy and the size of the equipment [22, 23]. In commercial application *o*-xylene loadings up to 80 g/m^3 (STP) are reached [107]. Catalysts in the form of rings or half rings are used. The catalyst is capable of processing both *o*-xylene and naphthalene or mixtures of the two [24, 25].

The Rhône-Poulenc process employs *o*-xylene as raw material. The crude product is subjected to a chemical posttreatment before being purified by two-stage distillation. The waste gas is incinerated [26, 27].

The ELF Atochem/Nippon Shokubai process uses a Nippon Shokubai catalyst for reacting *o*-xylene or naphthalene. With *o*-xylene, feed loadings of up to 75 g/m^3 (STP) are used industrially [107].

2.4.1.1. Catalyst and Reaction Mechanism

The oxidation of *o*-xylene and naphthalene is nowadays carried out almost exclusively in tubular reactors cooled by a molten salt. The spherical catalysts previously employed are only used in isolated cases in old plants. In modern plants ring-type catalysts have become established for

Scheme 1.

energy saving reasons [28], but catalysts on half-shell supports are also available [24, 25]. Commercial catalysts are normally composed of an inert ring-type support, made of silicate, silicon carbide, porcelain, alumina, or quartz measuring 5–10 mm in diameter, on which a thin active layer of a mixture of finely divided titanium dioxide and vanadium oxide is deposited. Compounds of antimony, rubidium, cesium, niobium, and phosphorus are added to improve the selectivity [29 – 35]. The use of a two-zone catalyst, i.e., a combination of catalysts with low activity with catalysts of higher activity, has become generally established [36]. For high loadings even three-zone catalysts are known. Some catalysts require addition of SO_2 for activation and longer service life [37, 38]. The reaction is driven to an almost quantitative turnover of *o*-xylene, to ensure low concentrations of disturbing byproducts (e.g., phthalide). It is summarized by the following equation:

The heat of formation is 1108.7 kJ/mol. Total combustion of *o*-xylene yields 4380 kJ/mol, i. e., almost four times the heat of formation of phthalic anhydride. Oxidation in tubular reactors produces a heat of reaction between 1300 and 1800 kJ/mol of *o*-xylene.

Scheme 1 shows the important byproducts found in the reaction product. Although the intermediate alcohol has so far not been detected, it is probable that the formation of phthalic anhydride passes through it. A standard interpretation of the course of the reaction is not available in the literature. All the conclusions are very dependent on the method of measurement used and on the experimental setup. So far no commercially used catalyst has been investigated in depth. There are also no literature data relating to aging phenomena. It is generally accepted that a redox mechanism, in which the selective oxidation proceeds at oxygen atoms in the lattice, is involved. Attempts are made in [39 – 59] to describe the course of the reaction.

According to literature data, it is now possible to achieve yields of 120 kg PA /100 kg *o*-xylene [35], but it is generally accepted that reactor yields exceeding 112–114 kg PA/100 kg *o*-xylene (calc. 100 %) are improbable on an industrial scale. This is equivalent to 80–82 % of stoichiometric yield. In *o*-xylene based processes, after allowing for the losses during condensation, dehydration, and distillation, pure phthalic anhydride yields of 110–112 kg PA/100 kg *o*-xylene may be expected.

The oxidation of naphthalene proceeds in accordance with the following equation:

The heat of formation is 1788 kJ/mol; total combustion of naphthalene yields 5050 kJ/mol. Depending on the yield achieved and the byproducts formed, a heat of reaction of 2100–2500 kJ/mol is expected. Possible side reactions are shown in Scheme 2.

Besides maleic anhydride, naphthoquinone is also formed as a byproduct, which requires a high performance of the purification stage. Data on the course of the reaction can be found in [60 – 63].

According to the literature, yields of up to 102 kg/100kg naphthalene are achievable in commercial plants, but the final product yields generally do not exceed 98 kg/100kg naphthalene, i.e., 85 % of theory.

Scheme 2.

2.4.1.2. Apparatus and Important Process Steps in the Gas-Phase Oxidation of *o*-Xylene

Procedure Employing an Ignitable Xylene–Air Mixture. The current objective of phthalic anhydride technology is essentially to limit energy consumption as far as possible. This is supplemented by efforts to construct as complete a system as possible for utilizing the steam produced in the plant, or alternatively by considering driving the air blower with a steam turbine [64, 65]. It is possible to save energy costs primarily by increasing the concentration of *o*-xylene in the process air, thus reducing the quantity of process air for the same capacity and increasing the steam yield [66].

It is possible to operate existing older plants, which were originally designed for loadings of 40 g/m^3 (STP), with *o*-xylene loadings of up to 80 g/m^3 (STP) by employing modern catalysts and modifying the reactor cooling system. The attainable increase in loading depends primarily on the feasibility of removing safely the increased heat of reaction from the reactor.

The lower limit of flammability is exceeded with a loading of ca. 44 g/m^3. In order to exceed the limit of flammability, it is essential to estimate the risks to the safety of the personnel and of the plants. It is impossible to completely eliminate the risk of ignition of an explosive mixture, but the equipment may be designed to be inherently safe, i.e., to withstand the highest possible pressure. Alternatively the equipment may be safeguarded by pressure relief devices so that pressure surges are relieved safely. Probability of ignition inside the catalyst is minimal as the autoignition temperature for phthalic anhydride is 580 °C, which is far above the temperature of the reaction.

Reactors. Figure 1 shows the development of the reactor types used to produce most of the phthalic anhydride worldwide. The reactor (A) was originally designed for the von Heyden catalyst and has a salt bath circulation pump and cooler fitted internally. This reactor gave way to reactor (B), which has an external cooling system [67]; the latter makes it possible to achieve a more advantageous temperature distribution for larger diameters. Superheated steam at pressures up to ca. 70 bar is produced in both reactors. The reactor (C), with an external cooling system in which saturated steam is produced, was developed for processes with higher loadings [68]. Reactor (D) is the common type for high-load processes. It uses radial salt flow for improved heat transfer. Reactors can be machined in one piece up to a diameter of 8 m, but can also be fabricated in segments and assembled on site [69]. Such reactors may incorporate more than 20 000 catalyst tubes and the construction of single-line plants having phthalic anhydride capacities exceeding 60 000 t/a is possible.

A) Reactor designed for the von Heyden catalyst; B) Reactor with an external cooling system; C) Reactor with an external cooling system in which saturated steam is produced; D) Reactor with radial salt flow (DWE-type)

Switch Condenser. A decisive factor for the efficiency of a phthalic anhydride plant is the performance of the condenser system in which the phthalic anhydride (which is contained in the process gas at a concentration of less than 1 vol %) must be condensed as completely as possible. Several separating methods are discussed in the literature. Processes in which the phthalic anhydride reaction gas is extracted by absorption into solvents or liquid phthalic anhydride [70 – 72] have not been exploited commercially.

Generally, switch condensers equipped with finned tubes which are alternately heated or cooled with a hot or cold heat-transfer medium are used. Solid phthalic anhydride is desublimated on the surface of finned tube bundles and subsequently melted out and collected in a storage tank.

A milestone in the improvement of switch condenser technology was the changing of the design from the upflow-type to the downflow-type. In the old switch condensers the reaction gas enters from the bottom and passes through the internal tube bundles from the bottom to the top. Most of the phthalic anhydride is deposited on the lowest bundle.

In the downflow type, the reaction gas enters at the top and leaves the condenser at the bottom. Most of the solid product deposits on the uppermost bundle, and the lower tube bundles are washed by molten phthalic anhydride during each melting cycle. In this way maleic acid and phthalic acid, which are byproducts of the process, are removed from the tubes. Phthalic acid and especially maleic acid are highly corrosive, and their iron salts, being pyrophoric, can cause fires by self-ignition.

Cooling and heating are usually carried out by a heat-transfer oil, fed through the finned tubes. Cooling with water and heating with steam has been proposed but has no obvious advantage.

Modern condensers can separate more than 99.5 % of the phthalic anhydride from the reaction gas. Improvements in the arrangement of the finned tubes resulted in reduced oil throughput and hence lower energy consumption compared with older condensers. The mechanical flexibility has been improved by changing the design, leading to a reduction of thermal stresses when switching from hot oil to cold oil and vice versa.

The increase of the capacities in the recent years have also affected the size of equipment, and switch condensers with a surface area of up to 4000 m^2 are being used today. At the beginning of the melting cycle, when the cold oil is replaced by hot oil, the system requires the highest amount of steam to maintain the oil temperature due to the heating-up of the swith condenser and to the heat of fusion of the phthalic anhydride. By installation of an additional heat reservoir connected to the hot oil system, it is possible to eliminate peaks and make the steam demand more uniform [73 – 76]. This effect is especially pronounced when the air blower is driven by a turbine using the steam from the same plant.

Treatment of Crude Phthalic Anhydride. To obtain high-purity phthalic anhydride, the crude product is subjected to thermal treatment before purification by distillation. Treatment with chemicals is generally necessary in the case of the crude product obtained from naphthalene in order to remove the byproduct, naphthoquinone, but is also used for products manufactured from *o*-xylene. Apart from sulfuric acid, which has been used for a long time, the following substances are used to destroy naphthoquinone: sodium hydroxide [77]; boric acid/sulfuric acid [78, 79]; potassium disulfide [80]; sodium carbonate [81 – 83]; potassium maleate [84]; and aliphatic polydienes [85, 86]. The most widely used method is probably simple heat treatment, but this is only suitable for

Figure 2. Purification of crude phthalic anhydride by distillation

crude products with low contents of impurities. It involves heating the crude product to 100–400 °C in a cascade of vessels. Normally the temperature is limited to 230–300 °C, and the retention times are 10–24 h. In the case of phthalic anhydride produced from *o*-xylene, the treatment is intended to remove water and low-boiling contaminants such as maleic anhydride and *o*-tolualdehyde. The destruction of phthalide is also achieved in pretreatments [87 – 90].

Distillation. The final purification of the crude phthalic anhydride is normally carried out in a continuous distillation system. Figure 2 shows schematically a typical distillation plant. The crude phthalic anhydride is first pretreated in a predecomposer where byproduct phthalic acid is converted to phthalic anhydride. The product is then introduced into a column in which the low-boiling constituents such as maleic anhydride and benzoic acid are concentrated at the head and removed. The bottoms are introduced into a distillation column, from which pure phthalic anhydride is removed from the head while the residue is discharged from the bottom.

2.4.2. Fluidized-Bed Oxidation

Of the many fluidized-bed processes for the oxidation of naphthalene, the process developed by Badger may still be in use today [91 – 93]. The capacity of such plants has been increased by injecting oxygen and air into the fluidized bed, thus enabling the naphthalene concentration to be increased.

Liquid naphthalene is injected directly at the bottom of the catalyst bed and evaporates immediately, distributing itself over the entire bed. Here it comes in contact with the catalyst and reacts with the atmospheric oxygen fed in via a distributor plate.

The vigorous agitation and mixing in the fluidized bed results in a uniform temperature being maintained throughout the bed, with the temperature being in the range 345–385 °C. The heat is removed by cooling tubes installed in the bed and is used to produce high-pressure steam. Any entrained catalyst is separated by cyclones and, after being retained in specially constructed ceramic filters, is blown back into the reactor. Several filter units are used, and one of them is always blown back with a stream of air in order to remove catalyst from the filter surfaces. Up to 60 % of the phthalic anhydride can be recovered in a liquid condenser, the remainder being desublimated in switch condensers. The crude product is then purified in a distillation column under vacuum. A proposal for regenerating a deactivated catalyst with SO_2 has been published [94].

Kawasaki Steel Corporation is working on the fluidized-bed oxidation of *o*-xylene. According to patent literature a stoichiometric yield of

up to 84 % at an *o*-xylene conversion of 94 % is reached [95 – 99].

2.4.3. Liquid-Phase Oxidation of *o*-Xylene

In the liquid-phase oxidation of *o*-xylene, a mixture of acetic acid, *o*-xylene, and catalyst, which consists mainly of Co, Mn, and Br, is fed to the first vessel in a cascade. The reaction, which is completed in the subsequent vessels, is initiated under pressure while the air is injected. The water produced by the reaction is removed in the first vessel by azeotropic distillation with *o*-xylene. The isomers of phthalic acid are removed from the reaction mixture, and the phthalic anhydride is obtained by crystallization. The crude product is subjected to a pretreatment which imposes special requirements because of the bromine content. Purification can then be carried out by distillation. The *o*-xylene must have an ortho isomer content $> 99\,\%$ if the process is to achieve high yields of 130 kg of phthalic anhydride from 100 kg of *o*-xylene. Companies such as Hüls have investigated the process [100] and, in addition, further work has been done on it by Standard Oil of Indiana [101].

Sisas has described a two-step process: in the first liquid-phase oxidation step crude*o*-toluic acid is formed with a yield of 1.19 g per gram of *o*-xylene at partial *o*-xylene turnover; unreacted *o*-xylene is recycled. The second step is the gas-phase oxidation of the *o*-toluic acid to phthalic anhydride. The overall molar yield based on *o*-xylene is up to 88 % [102].

2.5. Environmental Protection

Exhaust Gas. The exhaust gas from the switch condensers still contains an appreciable quantity of organic substances and therefore must be purified before it is discharged from the plant. Scrubbing with water in a scrubbing tower is suitable for extracting maleic anhydride, the main byproduct in the exhaust gas. In a recovery process, the organic acids from the scrubbed gas are concentrated in several scrubbing towers in which the scrubbing water is circulated until the concentration is ca. 30 %. The scrubbing solution is then worked up to recover maleic anhydride or fumaric acid. It is also possible to produce sodium maleate by adding sodium hydroxide or sodium carbonate [103].

The efficiency of the scrubbing depends on the sophistication of the equipment and the number of scrubbing stages. The concentration of all organic compounds can be reduced to < 150 mg per m^3 exhaust air discharged from the plant.

The main substance emitted from phthalic anhydride plants is carbon monoxide, which cannot be removed by exhaust-gas scrubbers. A plant emits about 1100 t CO per 10 000 t of phthalic anhydride produced, depending on the operating conditions.

Apart from scrubbing towers, two processes are at present available for purifying exhaust gas:

1) Thermal combustion at 650–850 °C which involves burning the organics and carbon monoxide in the presence of an oil-fed or gas-fed reverberatory flame.
2) Catalytic combustion at 250–450 °C, which normally does not require additional fuel. This process employs noble-metal or mixed-oxide catalysts.

Such plants are supplied, for example, by Haldør Topsoe in Denmark who employ their Catox process or by Engelhard who market the Torvex process.

A comparison of thermal and catalytic exhaust-gas combustion for phthalic anhydride plants is discussed in [104].

Catalyst. Depending on the operating procedure, the catalyst normally has a service life of 2–8 years, after which it must be replaced because its activity is too low. Used catalysts may be deposited, for example, at a secure landfill site; this depends on local regulations owing to the toxicity of the additives. As a result of various problems, washing and reusing the active material has so far been uneconomical, even though proposals are repeatedly being made in this connection [105, 106].

2.6. Quality Specifications and Analysis

The specifications of technically pure phthalic anhydride are listed in Table 2. A suitable method of determining the acids by gas chromatography is to form derivatives, for example, with diazomethane, but direct determination on

Table 2. Specifications of technical-grade phthalic anhydride

Property	Average value	Method	Specification limit
Purity, %	99.9	GC	99.8 min
Solidification point, °C	131.0	ASTM 1493–67	130.8 min
Maleic anhydride, %	0.03	GC	0.05 max
Benzoic acid, %	0.03	GC	0.1 max
Color index of melt (APHA)	5–10	ASTM 3366–74	20 max
Heat stability (APHA)	10–20	ASTM 3366–74	40 max

packed columns or capillary columns is also possible.

2.7. Economic Aspects

In 1996 world production capacity for phthalic anhydride was $> 3.7\times10^6$ t/a and this figure is expected to exceed 4.6×10^6 t/a in the year 2000. A remarkable increase in capacity is occurring in south-east Asia.

The world capacities for phthalic anhydride (10^3 t) in 1996 can be broken down as follows:

Western Europe	869
Eastern Europe	641
North America	568
South America	256
Japan	320
South Korea	260
India	153
Taiwan	95
Remainder of Asia	155
Africa and Near East	124

2.8. Storage and Transportation

Pure phthalic anhydride is a very stable compound and may be stored for a prolonged period in the molten state without any change in its properties. To prevent fires, it is recommended that storage containers and transportation are blanketed with nitrogen.

Molten phthalic anhydride is subject to the following safety and transport regulations:

EC directive no.	607–009–00–4
Symbols	X_i
R phrases	36/37/38
UN no.	3256
Packaging group	III
Transportation regulations	
GGVE/RID	3.61 c
GGVS/ADR	3.61 c
ADN/ADNR	3.61 c
GGV See/IMDG code	3.3, UN-No. 3256-PG III
IATA Dangerous Goods Regulation	3, UN-No. 3256

2.9. Uses

The most important application of phthalic anhydride is the production of plasticizers. The main uses of phthalic anhydride are [13]:

Plasticizers	55 %
Unsaturated polyester resins	14 %
Alkyd resins	15 %
Other	16 %

3. Phthalimide

3.1. Properties

Phthalimide [*85-41-6*], 1,3-dioxoisoindoline, $C_8H_5O_2N$, M_r 147.14, crystallizes from solution as white needles or prisms, while sublimation produces platelets. The compound is sparingly soluble in water (0.3 g at 20 °C, 0.9 g at 50 °C, 2.2 g at 100 °C in 100 g of water) and readily soluble in acetic acid, sodium hydroxide solution, or potassium hydroxide solution. Some physical properties of phthalimide are as follows:

Melting point	238 °C
Heat of combustion	3560 kJ/mol
Heat of fusion	187.6 J/g
Specific heat at 100 °C	1.21 J g^{-1} K^{-1}
Vapor pressure at	
120 °C	0.10 mbar
150 °C	0.95 mbar
180 °C	5.93 mbar
220 °C	30.7 mbar
254 °C	187.6 mbar
Flash point	214 °C
Ignition temperature	530 °C

With bases, phthalimide forms water-soluble salts, which react with halogens to form the corresponding *N*-chloro, *N*-bromo, or *N*-iodo compounds. These *N*-halo compounds are also obtained if alkali-metal phthalimides are reacted with hypochlorous or hypobromous acid. When the *N*-halo compounds are heated, isatoic anhydride [*118-48-9*] or anthranilic acid (*o*-aminobenzoic acid) [*118-92-3*] is formed in a Hofmann degradation [108, 109]. The reaction of alkali-metal phthalimides with alkyl halides to give *N*-alkyl phthalimides, and subsequent hydrolysis or hydrazinolysis affords primary amines (Gabriel synthesis) [110]:

3.2. Production

Phthalimide is produced almost exclusively from phthalic anhydride and ammonia, but processes based on phthalic anhydride and urea or oxidative ammonolysis of *o*-xylene are also known.

3.2.1. Production from Phthalic Anhydride and Ammonia

The continuous processes for producing phthalimide are particularly important industrially. One of the continuous processes is carried out in an externally heated, vertical reaction tube filled with packing material [111]. A gas-tight connection links the bottom of the reaction tube to a sublimation chamber from which a discharge arm discharges the phthalimide through a slot by means of a screw conveyor. The exhaust gases are discharged from the sublimation chamber via built-in baffles.

Molten phthalic anhydride and excess ammonia are continuously fed into the reaction tube at the top and are reacted at 250–280 °C. The reaction gases are cooled to 170–180 °C in the sublimation chamber, and solid phthalimide is deposited and discharged. Water and excess ammonia are removed via an exhaust-gas pipe. A 98 % yield of phthalimide is obtained with a purity of 99 %.

Another continuous process for producing phthalimide from phthalic anhydride is a countercurrent process [112]. Molten phthalic anhydride is continuously fed to the head of a reactor while ammonia is continuously fed to the bottom. The temperature increases from $\geq$ 150 °C at the top of the reactor to a maximum of 270 °C at the bottom. The molten phthalimide emerging from the bottom of the reactor with a purity of 99 % is cooled and flaked or dissolved in aqueous alkali, and supplied as a starting material for further syntheses, e.g., to produce anthranilic acid.

The exhaust gas from the head of the reactor, which is composed of water vapor, sublimed phthalimide and phthalic anhydride, and ammonia, is fed to the bottom of a scrubbing column where it is scrubbed in countercurrent with molten phthalimide from the bottom of the reactor. The melt taken from the bottom of the scrubbing column, which contains unreacted phthalic anhydride, is returned to the reactor, while the exhaust gas from the scrubbing column, which contains predominantly water vapor and phthalimide, is dissolved in aqueous alkali, and the solution is used to produce anthranilic acid.

3.2.2. Production from Phthalic Anhydride and Urea

Solvent-Free Process. A mixture of phthalic anhydride and urea is introduced into a heatable, tiltable reaction vessel. Mounted on the cover of the vessel is an extraction tube for the reaction gases, CO_2 and water vapor. The reactor is heated to 130–140 °C until the contents are molten, and as soon as the elimination of CO_2 and water starts, heating is ceased. The heat of reaction causes the temperature to rise to ca. 160 °C. The reaction is complete when the contents of the reactor have swelled to several times their original volume as a result of foaming and have solidified.

The cover of the reactor is then removed. The pure phthalimide is discharged into a collecting vessel by tilting the reactor, is cooled and ground, and used without further treatment. The yield is > 90 % [113].

Production in a Solvent. Phthalic acid or phthalic anhydride can be reacted with urea in the presence of a solvent to form phthalimide. Suitable solvents are substituted and unsubstituted hydrocarbons and aromatics and heteroaromatics such as *n*-propylbenzene, cumene, 1,2-dichlorbenzene, and picoline. Urea must be insoluble in the reaction medium, while phthalic acid or phthalic anhydride must be only slightly soluble. The reaction is carried out below the boiling point of the solvent, normally at 160–170 °C. When the reaction is complete, the pure phthalimide is filtered off and washed with water. The yield is 95–100 % [114].

3.2.3. Production from *o*-Xylene

o-Xylene is reacted in the gas phase with ammonia in the presence of a metal-oxide catalyst as oxygen donor. Phthalimide, phthalamide, or phthalonitrile can be selectively produced, depending on how the reaction is controlled [115].

3.3. Uses

Phthalimide is of industrial importance as the starting material for producing anthranilic acid by Hofmann degradation, and a large number of primary amines can be produced by the Gabriel synthesis. Phthalimide is an intermediate in the production of agricultural pesticides and wood preservatives, pigments, and pharmaceuticals.

4. Phthalonitrile

4.1. Properties

Phthalonitrile [*91-15-6*], 1,2-dicyanobenzene, 1,2-benzenedicarbonitrile, $C_8H_4N_2$, M_r 128.14, is a crystalline powder having a faint grayish yellow color and a slighty aromatic odor, similar to benzonitrile. Phthalonitrile was first described in 1896 when it was isolated during the diazotization of 2-aminobenzonitrile.

The compound is sparingly soluble in water (ca. 1 g/L) and soluble in acetone, nitrobenzene, and benzonitrile. It cannot be distilled and polymerizes if heated above the melting point. It is not explosive and is difficult to ignite, but the dust can explode. Some physical properties of phthalonitrile are as follows:

Melting point	141 °C
Heat of combustion	4013 kJ/mol
Heat of evaporation	67 kJ/mol
Specific heat at 30 °C	1.30 J g^{-1} K^{-1}
Vapor pressure at 20 °C	0.05 mbar
Density	1.238 g/cm^3
Apparent density	ca. 0.5 g/cm^3
Flash point	162 °C

4.2. Production

Phthalonitrile is produced commercially from *o*-xylene, phthalic acid, phthalic anhydride, phthalamide (**1**), or phthalimide (**2**).

1

2

4.2.1. Production from *o*-Xylene

Ammoxidation. In a single-stage continuous process, *o*-xylene is converted to phthalonitrile by reaction with ammonia and oxygen in the gas phase in a fluidized-bed reactor. Generally, metal oxide mixtures containing vanadium, antimony, chromium, and molybdenum, with further active components such as iron, tungsten, and alkali-metal oxides, on an alumina or silica support are used as catalysts [116 – 123].

The course of the reaction and the industrial importance of ammoxidation have been described in depth in [124 – 126]. The commercial process of producing phthalonitrile from *o*-xylene by oxidative ammonolysis is as follows [127, 128]: A gaseous mixture of *o*-xylene, NH_3, and O_2 is passed through a distributor plate into a fluidized-bed reactor. Either a vanadium oxide–antimony oxide catalyst or a vanadium oxide–chromium oxide catalyst on an alumina support is used. The optimum temperature for pressureless ammoxidation is 480 °C. Temperatures below 480 °C lead to the formation of up to 10 % of the undesirable byproducts phthalamide and phthalimide. Above 500 °C, ammonia begins to burn. The cooling elements incorporated in the fluidized bed make it possible to keep the temperature constant despite the large heat of reaction. The hot reaction gases from the reactor are quenched in a product settler with an aqueous suspension of phthalonitrile. After settling and cooling, the phthalonitrile is separated in decanters and dried.

The phthalonitrile produced in this way, which contains < 0.1 % of acid and phthalimide and < 0.1 % water, can be processed directly without further purification to yield phthalocyanine pigments. The yield is 80–85 %.

Ammonia is removed from the gas mixture emerging from the product settler (the latter contains NH_3, CO_2, CO, N_2, and traces of HCN) in an ammonia recovery plant, and the exhaust gas is burnt. The ammonia is returned to the process. Unreacted *o*-xylene and the intermediate *o*-toluonitrile can be worked up to isolate *o*-toluonitrile or can be fed back into the fluidized-bed reactor for complete conversion to phthalonitrile.

Oxidative Ammonolysis. The continuous production of phthalonitrile from *o*-xylene by oxidative ammonolysis has been studied in a pilot plant [115, 129]. In this process *o*-xylene is reacted with ammonia in the presence of a metal-oxide catalyst in the gas phase at 350–450 °C using a vanadium oxide–molybdenum oxide catalyst on an alumina or silica support. The oxidation medium is the metal-oxide catalyst, part of which is continuously removed, reoxidized, and then fed back into the reactor. The phthalonitrile is quenched from the hot reaction gases in the same way as in the ammoxidation process, while byproducts such as *o*-toluonitrile, phthalamide, and phthalimide are fed back into the phthalonitrile reactor or can be converted into phthalonitrile in a second reactor at 400 °C in the presence of NH_3 on a boron phosphate–alumina catalyst.

Ammonia is recovered from the residual gas mixture, which contains NH_3, CO_2, CO, N_2, and traces of HCN, and fed back into the process. Noxious gases such as CO and HCN are burnt in the regenerator and N_2 and CO_2 are eliminated from the process.

4.2.2. Production from Phthalic Acid Derivatives

Phthalonitrile can be produced from phthalic acid, phthalic anhydride, phthalamide, or phthalimide by reaction with ammonia and elimination of water at 300–500 °C in the gas phase in the presence of a catalyst.

Catalysts mentioned in the patent literature are the oxides of thorium, copper, beryllium, zirconium, or tungsten on a silica, alumina, or phosphate support, or on silicates, borates, and basic alumina.

Molten phthalic anhydride heated to ca. 160 °C is evaporated in a heating apparatus into which preheated circulating gas containing NH_3 in a concentration of ca. 90 % is also fed. The gas mixture is reacted under virtually unpressurized conditions at 350–400 °C in a fixed-bed reactor downstream of the heating apparatus using an Al_2O_3 catalyst. The reaction gas emerging from the reactor is quenched with water, and the phthalonitrile is separated from the aqueous suspension in decanters and dried. The concentration of NH_3 in the circulating gas is kept at ca. 90 % by adding NH_3.

Numerous other production methods have been described [130, 131], but have no commercial significance. For example, phthalonitrile can be prepared by eliminating water from phthalamide in the presence of acid halides such as phosgene or thionyl chloride. To prevent hydrolysis of the phthalamide by the acid formed, diluents such as benzene or chlorobenzene are added

or the acids are bound by tertiary amines such as *N,N*-diethyl-*o*-toluidine or pyridine. It is also possible to use acylated secondary amines such as *N*-methylformamide.

4.3. Uses

Phthalonitrile is used as a starting material for producing phthalocyanine pigments (→ Phthalocyanines), fluorescent brightners, and photographic sensitizers.

5. Phthalates

A wide variety of dialkyl phthalates are produced and marketed (Table 3).

In the early 1900s, the availability of monohydric alcohols was limited to those with a chain length of up to four carbon atoms. This resulted in the development and manufacture of four esters; e.g., diethyl phthalate (DEP) was used as a heat-transfer oil, and dibutyl phthalate (DBP) was used to reduce the hygroscopicity of explosives. Both DEP and DBP were also used as carriers in the perfume industry [132].

Also at this time camphor was being used as a plasticizer for cellulose nitrate and cellulose acetate. In the early 1920s it was found that phthalates could replace the expensive plasticizer camphor. This increased the demand for phthalates [132]. In 1937, the "Chemiker Taschenbuch" [133] listed seven phthalates for use as plasticizers. The late 1920s saw the start of the development of poly(vinyl chloride), PVC. PVC is rigid and brittle at ambient temperature. However, when plasticized it was found to be suitable for replacing natural rubber [132]. In 1929 a U.S. patent for plasticized PVC was granted to Ostromislenski [134], and Kyrides applied for U.S. patent for the use of di-2-ethylhexyl phthalate (DEHP) as plasticizer for PVC, which was granted in 1933 [135].

The most important phthalates are DEHP, the standard general purpose plasticizer for PVC, followed by DINP and DIDP [136]. In trade, DEHP is also referred to as DOP. Besides the phthalates listed in Table 3, phthalate blends and coesters are used for special applications [137].

5.1. Physical and Chemical Properties

All phthalates listed in Table 3 are clear, oily liquids at room temperature. They are soluble in common organic solvents and are miscible with other PVC plasticizers. When added to plastics and resins, they improve the workability during fabrication, modify the properties, or give rise to new improved properties not exhibited by the original material [138].

Some of the important properties of plasticizers are listed below. These properties are influenced by the manufacturing process and can vary significantly. The values given are typical ranges in which commercial products are available. The analytical methods are listed in Table 4.

APHA color	5–60
Acid number, mg KOH/g	0.02–0.1
Water content, wt %	0.05–0.1
Purity, area % or wt %	99.0–99.5
Odor	odorless or low

5.2. Raw Materials

Phthalic anhydride (PA) and monohydric alcohols are generally the raw materials for phthalates of commercial significance. Phthalic anhydride is mainly used in the molten form. The alcohols are based on the C_2–C_4 olefins, which are produced in either the steam cracking process or in petrochemical plants. These alcohols can be produced by (1) oligomerization or Ziegler synthesis followed by hydroformylation and hydrogenation, or (2) by aldol condensation with hydrogenation (e.g., the production of 2-ethylhexanol from propylene). The linear or slightly branched C_6 to C_{11} alcohols are based on ethylene. Isononanols are produced from the C_4 fraction of the steam cracker output or from C_8–C_9 olefins from a poly gas unit (olefin oligomerization) [133].

5.3. Production

The formation of phthalates is as follows:

Table 3. Commercially important phthalates

Chemical denomination	Code 1* DIN 7723	CAS registry no.	M_r	Viscosity at 20 °C, mPa · s	Density at 20 °C, g/m^3	Refractive index at 20 °C
Dimethyl phthalate	DMP	[*131-11-3*]	194.19	18	1.191	1.516
Diethyl phthalate	DEP	[*84-66-2*]	222.24	13	1.117	1.502
Dibutyl phthalate	DBP	[*84-74-2*]	278.35	21	1.047	1.493

* Codes in parentheses are used in English.
** DINP types are based on different branched isononyl alcohols.

The first step, alcoholysis of PA to give the monoester, is rapid and goes to completion. The reaction generally starts at elevated temperatures and proceeds exothermically.

The second step is the conversion of the monoester to a diester with the formation of water. This is a reversible reaction and proceeds more slowly than the first, thus determining the overall rate of reaction. To shift the equilibrium towards the diester, the water of reaction is removed by distillation. The rate of reaction can be influenced by the choice of catalyst and the reaction temperature. For fast conversion rates, high reaction temperatures are generally used. However, these are influenced by the boiling point of the alcohol and/or the type of catalyst.

Sulfuric acid [132], methanesulfonic acid [139, 140] and *p*-toluenesulfonic acid [132] are effective esterification catalysts [140]. Sodium hydrogensulfate [132] or the monoester itself [132, 141] can also be used. Acid catalysts can be used for esterification reactions at temperatures up to 140–165 °C [132, 141]. Their use above these temperatures results in undesirable side reactions such as alcohol degradation with the formation of olefins, ethers, and colored products [141]. Acid catalysts are the preferred catalysts for the manufacture of phthalates from low-boiling alcohols up to C_4. Acid catalysts have also been used for the production of phthalates from higher alcohols in the presence of a water entrainer, e.g., aromatics or chlorinated hydrocarbons. Alternatively, the esterification can be carried out at reduced pressure, which allows the distillation of a water–alcohol azeotrope at low temperature; however, longer reaction times are required.

The autocatalytic esterification [132] can be carried out at temperatures above 200 °C, but the conversion to diester is not complete, and the recovery of unreacted monoester is necessary.

Currently, nearly all major phthalate producers use amphoteric catalysts for the esterification of high boiling alcohols. The first claim for the use of titanates as esterification catalysts was made in 1955 in the United States [142]. Since then titanates and tin(II) compounds have

Figure 3. Simplified flow sheet for the production of phthalates. Terms in parentheses are optional.

been widely used as esterification catalysts [140, 143 – 145].

The reaction temperatures for the amphoteric catalysts are about 200 °C [143]. At this temperature side reactions are minimized, and the alcohol can be recycled without purification. By using this type of catalyst, over 99.5 % conversion to diester can be achieved [143 – 145].

Phthalates can be produced continuously [132, 141] or batchwise. The process steps outlined in Figure 3 are applicable to both methods. Variations are possible depending on the catalyst used, the reactant alcohol, and the process type.

For batch processes the reactor is usually a stirred vessel made of stainless steel, which can be rapidly heated to maintain a high distillation rate during diester formation for removing the water of reaction.

For the esterification of the water-soluble C_1–C_4 alcohols, the overhead vapors of the reactor are fed into a rectification column where the evaporated alcohol is dried before it is recycled to the reactor. If higher alcohols of very low water solubility are used, the vapors from the reactor can be fed directly into a condenser which drains into a alcohol–water separator. The water is separated here by settling and the alcohol is recycled to the reactor.

Usually a 20–25 % excess of alcohol is used [140]. The catalyst can be added with the alcohol. Amphoteric catalysts are preferably added after monoester formation has taken place at 160 °C [140]. PA can be charged as flakes or molten. The use of molten PA reduces the cycle time of a batch.

After charging the raw materials heating is continued, e.g., for DOP to a maximum of 224 °C [145]. In order to remove the water of reaction, a good boil up rate is maintained. This can be achieved by adjusting the pressure with a vacuum source. The water of reaction can also be stripped off by an inert gas sparge. When the required acid number is achieved, the excess alcohol is removed under reduced pressure [145].

The purification procedure required after the esterification is determined by the catalyst type. For acid catalysts, neutralization with aqueous caustic soda is necessary. However, traces of alkali remain in the organic phase, and therefore a water wash after the neutralization step is advisable.

Titanates are generally removed by alkaline hydrolysis. The product is cooled to ca. 100 °C [140], and lime or soda ash or sodium hydroxide are added with water. The mixture is stirred and

the water is then removed by vacuum distillation.

After neutralization, residual alcohol is removed by steam distillation [140]. The temperature, pressure, and steam for injection are adjusted so that the product after this treatment is nearly alcohol free and dry. The final filtration is performed with a rotary vacuum filter or plate and frame filters. If the hydrolyzed catalyst was not removed with the water phase in the neutralization step, the catalyst can be removed in the filtration step by adding a filter aid.

The continuous BASF process described in [132, 141] can be carried out autocatalytically or preferably by using an amphoteric catalyst. The esterification is carried out in a multistage cascade of agitated vessels. The reaction mixture leaving the last reactor is pumped to a vacuum flashing chamber to recover the excess alcohol [132]. To remove the catalyst, the crude ester is treated with a mild aqueous alkali solution in a mixer/settler system. To remove residual volatiles such as water, alcohol, and other low-boiling compounds a steam distillation is carried out under reduced pressure. For the final treatment a filter aid is added. The product is subjected first to coarse and then to final filtration.

5.4. Environmental Protection

The wastewater from phthalate processes is contaminated with phthalates, alcohols, and other organic compounds. Therefore, the process wastewater must be treated before discharging to a municipal system or a water body. Local regulations dictate the treatment and disposal of this water. Generally, biological treatment is required. Studies on phthalates have shown that they can be biodegraded by many species of bacteria [146 – 148]. In Germany only three phtha-lates (diethyl phthalate, diallyl phthalate, benzyl butyl phthalate) are listed in the catalog for water-endangering materials [149]. They are classified as materials with moderate hazard potential (WGK 2).

In the United States and Canada there are no current regulations limiting the concentration of phthalates in wastewater.

In the TA Luft [150], only DOP is mentioned as material of class II (intermediate danger potential). The other phthalates have been classified according to the hazard potential for the environment by the rules given in [150]. Exxon [146] lists the C_4–C_{11} phthalates, with the exception of DOP, in class III. Because of their low vapor pressure, the phthalates easily meet the concentration limits for phthalates specified by TA Luft.

Owing to the high working temperatures, air emissions from compounding and extrusion processes for flexible PVC generally have high phthalate concentrations. Therefore emission controls may be required for these discharges. Exxon [146] gives the following data for the environmetal levels of DBP and DEHP:

- Fresh and estuarine/sea waters: 10 and 0.7 ppb, respectively
- Sediments: a few ppb up to 100 ppm
- Air: 3 ng/m^3 over the sea and up to 130 ng/m^3 in cities.

Detailed information on DBP and DEHP distribution in the environment are given in [147, 148].

In North America, waste containing DEHP and DBP is regarded as hazardous waste and must be disposed off in a secured landfill site.

5.5. Quality Specifications

For manufacturing flexible plastics the following properties are important for the selection of a plasticizer [134]: (1) compatibility with plastics, (2) solvating temperature (a measure of the solvating capability on plastics), (3) efficiency for plasticizing, (4) volatility in plastics, (5) extractability and diffusion losses in plastics, and (6) electrical properties. The properties required in the final products determine the type and the quality specification of the plasticizer.

For manufacturing flexible PVC for blood bags or other goods in medical application the plasticizer used (e.g., DEHP) should have a purity of min. 99.5 %, a low alcohol content, a low acid number (max. 0.02 mg KOH/g), and no odor [151].

Flexible vinyl sheets used for automotive interior trim should be plasticized with a phthalate that ensures low fogging of the interior windshield. Also low-temperature flexibility, light and thermal stability, and processability

are required. BASF [152] recommends a low-branched DINP or a HNUP for this application.

Phthalates used for plasticizing PVC for wire, cable, and conductor sheathing need high electrical volume resistivity. Products with volume resistivities $> 1.0\times10^{11}\ \Omega\cdot$cm at 20 °C are required. Typical resistivity of DOP is 1.0×10^{11}, and of DIDP $1.0\times10^{12}\ \Omega\cdot$cm.

Quality tests are carried out both on the phthalate itself and on the plasticized polymers. Table 4 lists standards for testing phthalates as PVC plasticizers.

Nowadays, almost all demands of plasticizers for use in flexible plastics can be met by phthalates.

Table 4. Standards for testing of phthalates

Property	Methods	
	DIN	ASTM
Phthalates		
Viscosity at 20 °C	51 561	D 445
Density at 20 °C	51 757	D 1045
Refractive index at 20 °C	51 423	D 1218–61
APHA color	ISO 6271	D 1209
Acid value	53 402	D 1045
Pour point	ISO 3016	D 97–57
Water content	51 777	D 1364
Purity	gas chromatography	
Plasticized PVC		
Solvating temperature	53 408	
Tensile strength	53 455	D 412
Elongation at break	53 455	D 412
Brittleness temperature	53 372	D 746
Clash & Berg torsion stiffness at 310 N/mm^2	53 447	D 1043
Shore B hardness	53 505	D 2240
Volume resistivity at 25 °C	53 482	D 1169

5.6. Storage and Transportation

Because phthalates are neutral liquids they can be stored in carbon steel tanks. The more expensive stainless steel or aluminum alloy tanks are also used. All phthalates have a flash point above 100 °C. Thus bulk storage of phthalates does not require any special fire protection equipment [153]. German regulations [154] classify phthalates as having an endangering potential to water. Therefore storage tanks have to be installed in a diked area which has a containment capacity of the largest tank. Detailed proposals for storing phthalates are given in [155]. Phthalates can be stored indefinitely and can withstand tropical conditions.

Phthalates are transported in tank cars, tank trucks, ships, or mild steel drums. Canada and California have special labeling requirements for DBP and DEHP.

5.7. Uses

The C_1–C_4 phthalates including DMEP and DBEP are mainly used as plasticizers for cellulosic resins and some vinyl ester resins. DBP and BBP are fast-fusing plasticizers for PVC and are mostly used in combination with DEHP. C_4 phthalates are also appropriate plasticizers for nitrocellulose lacquers.

DEHP, DINP, DIDP are the general purpose plasticizers for PVC in most applications (see also → Plasticizers). For wire and cable, DIDP is preferred. The linear phthalates, e.g., 711P or 911P, are used for PVC in various applications. They are less volatile and confer better low-temperature properties than general-purpose phthalates. DUP and DTDP are recommended for use in wire insulation for use at ca. 100 °C.

87 % of the phthalates produced are used for formulating flexible PVC, which is consumed for manufacturing the following goods [156]:

Wire and cable	25 %
Film and sheeting	23 %
Flooring	15 %
Profiles and tubing	10 %
Plastisol spread coatings	11 %
Other plastisols	8 %
Miscellaneous (shoe soles, blood bags, gloves)	8 %

5.8. Economic Aspects

The major phthalate producers in Europe, the United States, and Japan are listed in Table 5. The capacities of these companies range from 70 000 to 350 000 t/a.

In 1988 world consumption of plasticizers, including nonphthalates, was 3.85×10^6 t [157]. Based on these figures and uses in other applications, world consumption for phthalates is estimated at 3.25×10^6 t, of which DEHP accounts for ca. 2.1×10^6 t. The estimated total consumption of all phthalates and consumption of DEHP (in 10^3 t) by geographic region is:

	Total	DEHP
Western Europe	900	465
North America	730	155
Eastern Asia	530	490
Japan	320	245
Others	720	765
World total	3250	2120

Prognoses for the world market show an annual increasing demand of ca. 2.5 %.

Table 5. Major phthalate producers and their trade names

Company	Location	Trade name
Aristech Chemical Corp.	United States	PX
ATOCHEM	Europe	Garbeflex
BASF	Europe, United States	Palatinol
BP Chemicals	Europe	Bisoflex
Chemische Werke Hüls	Europe, United States	Vestinol, Nuoplaz
Eastman Chemical	United States	Kodaflex
Enichimica	Europe	Sicol
Exxon Chemical	Europe, United States	Jayflex
Hoechst	Europe	Genomoll
ICI	Europe	Hexaplas
Kyowa Hakko	Japan	Kyowacizer
Mitsubishi Kasei Vinyl	Japan	
Neste Chemicals	Europe	
New Japan Chem.	Japan	

6. Toxicology

6.1. Use of and Exposure to Phthalic Acid and Derivatives

Phthalate esters, phthalic acid, phthalic anhydride, phthalimide, and phthalonitrile are intermediates that are produced and further used in industry under well-controlled conditions. Occupational exposure may occur but is expected to be low. Exposure of the general public is low and negligible. However, the case of phthalate esters is different because these are generally used as plasticizers, not only for a wide range of products for industrial use such as resins, paints, electrical cable, and equipment lining, but also for numerous consumer products like PVC floor tiles, shoes, rubber boots, gloves, and household plastic materials including food containers. Plasticizers are also contained in toys and in medical equipment such as blood bags, infusion lines, and devices for hemodialysis and extracorporeal membrane oxygenation (ECMO). Thus, both occupational exposure of workers during production and the exposure of the general public may occur. The highest levels of exposure are expected for children and patients undergoing intensive medical treatment. This promoted intense investigation of the exposure to and the mode of action of phthalate esters. The most prominent — diethylhexyl phthalate (DEHP) — may be regarded as a model phthalate ester and is therefore described below in more detail.

6.2. Toxicological Profiles

6.2.1. Phthalic Acid

Only few investigations exist; however, the toxicity appears to be low. Acute toxicity (LD_{50}, mouse, i.p.): 550 mg/kg [158].

Metabolism. Most of the material is excreted in the urine, either directly (as in dogs) or partially conjugated (as in rats and rabbits). A minor part may be decarboxylated and excreted as benzoic acid [159].

6.2.2. Phthalic Anhydride

Phthalic anhydride is an inhalation allergen and may cause occupational asthma in exposed persons [160 – 164]. Hexahydrophthalic acid showed also respiratory sensitizing properties [163].

Acute toxicity data indicate minor toxicity. Acute toxicity: LD_{50}, rat, oral: 1500–4000 mg/kg [165]; LC_{50}, rat inhalation: > 210 mg m^{-3} h^{-1} (dust) [166]; LD_{50}, rabbit, dermal: $>$ 10 000 mg/kg [166]. Dermal irritation: nonirritating or slightly irritating in rabbit skin [165]. Eye irritation (rabbit): irritating [165, 166]. Dermal sensitization: sensitizing in the mouse ear swelling test [162].

Subacute Toxicity. Feeding experiments with 250, 1000, and 3800 ppm in the diet (17, 67, and 253 mg kg^{-1} d^{-1}) were tolerated for 28 d without significant effects [166]. Gavage experiments in female rats, beginning with 20 mg kg^{-1} d^{-1} and subsequently increasing doses up to 4800 mg kg^{-1} d^{-1} over a period of 8 weeks, caused toxic effects on the kidneys and the gastric mucosa at doses exceeding 1200 mg kg^{-1}

d^{-1} [167]. Inhalation experiments with sublimed material in rats, mice, rabbits, and cats showed some irritation and impaired respiration at 10 000 mg/m^3 for 4 h per day for two weeks [165]. In female guinea pigs, vapor concentrations of 615 mg/m^3 for 30 min per day over 4 and 8 d caused irritative effects on the eyes and respiratory tract [167]. Repeated inhalation of pure phthalic anhydride dust in concentrations of 8.5 mg/m^3 for 3 h per day for several periods of 4 consecutive days, alternating with 10-d recovery periods for a total experimental period of 8 months, caused irritation of the respiratory tract and frequent pneumonias [167].

Genotoxicity. No mutagenic effects were detected in the Ames test. No sister chromatid exchanges or chromosome aberrations were found in CHO cells. All experiments were conducted with and without metabolic activation [168, 169].

Chronic Toxicity and Carcinogenicity. Long-term bioassays with 7500 and 15 000 ppm in the diet of rats (500 and 1000 mg kg^{-1} d^{-1}) did not lead to an increased tumor incidence compared to control animals. Similarly, mice dosed with 3500 and 7100 mg kg^{-1} d^{-1} for 32 weeks and with 900 and 1800 (females) or 1800 and 3600 (males) mg kg^{-1} d^{-1} for a further 72 weeks did not respond with an increase of tumors [170, 171].

Reproductive Toxicity. Only screening experiments with intraperitoneal injection in CD-1 mice have been reported. 80 mg/kg injections were carried out from gestation days 8 to 10 or 11 to 13. Malformations (cleft palates, malformations of ribs and vertebrae) were detected at doses $\geq$ 55.5 mg kg^{-1} d^{-1} [172 – 174]. The experiments are inconclusive for the quantitative assessment of a teratogenic risk, since the exposure route was artificial and mice are prone to respond to experimental stress with these types of malformations.

6.2.3. Phthalimide

Few data exist; however, a low toxicity may be assumed. The material is hydrolyzed to phthalic acid and ammonia [175].

Acute toxicity. LD_{50}, (rat, oral): $>$ 5000 mg/kg (Bayer AG (1978), cited in [176]); LD_{50}, (mouse, oral): 5000 mg/kg [177]. The material was not irritating to the rabbit skin and eye [176]. No data on sensitizing properties are known to exist.

Repeated-Dose Toxicity. There were no substance-related effects in male and female rats after inhalation of the material at 0.051, 0.154, and 0.523 mg/L (4 weeks, 6 h/d, 5 d/week) regarding mortality, body weight gain, clinical chemistry including hematology and urinalysis, or gross organ changes (IBT (1979); cited in [176]). No long-term studies are known to exist.

Genotoxicity. Phthalimide was not genotoxic in an Ames test performed according to the OECD test guideline using *S. typhimurium* strains TA98, TA100, TA1535, and TA1537 at concentrations of 8–5000 μg per plate, with and without metabolic activation (Bayer AG (1993); cited in [176]).

Reproductive Toxicity. No reliable studies are reported in [176].

6.2.4. Phthalonitrile

Acute Toxicity. LD_{50}; (rat, oral): 30–125 mg/kg [178, 179]. No irritation of rabbit skin (BASF AG (1969); cited in [178, 179] or eye (BASF AG (1993); cited in [178]) was noted. Medical records of workers involved in the production and use of phthalonitrile do not indicate sensitizing properties (BASF AG (1995); cited in [262]).

Repeated-Dose Toxicity. Neurotoxicity was noted in rats and mice following repeated dosing in the form of convulsions and increased excitation [178]. Increased activity and body weight decreases were seen in a 13-week rat neurotoxicity study at 10 and 25 mg kg^{-1} d^{-1}. There was no histopathological correlation to the behavioral changes. The NOAEL was 3 mg kg^{-1} d^{-1} in this study (Bio Research (1994), cited in [178]). Epileptiformic convulsions lasting minutes were observed in workers after occupational exposure with a latency period of several hours to days [180]. Clinical examinations,

clinical chemistry, hematological parameters, neurological studies, and EEG studies detected no abnormal findings in 81 workers who had been exposed for an average of 8.5 years, 11 of whom had suffered from acute intoxications (Kleinsorge et al. (1979); cited in [178]). Also dermal exposure may be relevant [179]. Since the material does not appear to be metabolized to cyanide, the typical measures taken against cyanide intoxications are not promising.

Genotoxicity. The material does not cause mutagenic effects in the Ames test [181] and the CHO/ HGPRT gene mutation assay [182]. The substance was negative in the mouse micronucleus test in vivo (LMP (1987); cited in [178]). Chromosomal aberrations were not increased in 20 workers, seven of whom had experienced acute intoxications (Fleig and Thiess (1979); cited in [178]).

Carcinogenicity. After oral and subcutaneous administration to rats and mice, and after percutaneous administration to mice, induction of leukemia was reported. The study description is, however, vague and does not allow a conclusive assessment [183].

6.2.5. Phthalate Esters

Diethylhexyl phthalate has been most extensively investigated, due to the large production volume and widespread use. The following sections on the general toxicological profile of phthalate esters therefore focus on DEHP as the lead substance. However, significant differences between groups of phthalate esters of varying chain lengths need consideration. Generally, according to the length of the linear alkyl backbone of the alcohol moiety, groups of low (C_1–C_3), intermediate (C_4–C_6), and high molecular weight (C_7–C_{13}) phthalate esters are distinguished.

6.2.5.1. Metabolism and Toxicokinetics

Phthalate esters in general are rapidly hydrolyzed to the corresponding monoesters and the respective alcohol in the intestine [184]. These are readily absorbed from the gut [185], with some species difference in absorption and excretion. Short-chain phthalates such as dimethyl phthalate are either excreted unchanged in the urine or completely hydrolyzed to phthalic acid and excreted [186].

The pattern of DEHP metabolites in the urine has been elucidated [187, 188]. MEHP appears in native or — depending on the species — in glucuronidated form (at the carboxylate moiety) in the urine along with degradation products from ω-and ω-1-oxidation in the alcohol side chain. ω-Oxidation leads to a carboxylic moiety at the C-terminal site of the alcohol chain. ω-1-Oxidation leads to the 5-hydroxy and 5-keto derivatives of MEHP [188]. The latter was shown to be the metabolite ultimately responsible for peroxisome proliferation [189]. The ω-1-oxidative pathway is more pronounced in the rat than in the cynomolgus monkey [190].

The metabolism of DEHP is shown in Figure 4.

The liberated primary alcohols may be oxidized to the respective aldehyde and carboxylic acid via enzymatic reactions catalyzed by alcohol and aldehyde dehydrogenases. The fatty acids are further degraded in the intermediary metabolism, i.e., the fatty acid and citrate cycles. This pathway holds true for linear primary alcohols and for primary alcohols which are methyl-branched at even-numbered positions, whereas branched primary alcohols with a methyl substituent at an odd-numbered position and 2-ethyl-branched alcohols do not undergo β-oxidation. Similarly, secondary and tertiary alcohols are not metabolized to the fatty acid and aldehyde, respectively. When β-oxidation does not allow rapid metabolism, alternative reactions (chain hydroxylation and conjugation) occur prior to urinary excretion [191].

Di-*n*-octyl phthalate was similarly metabolized, i.e., the monoester was formed and side-chain oxidations occurred. Phthalic acid was also detected in minor quantities [192].

Toxicokinetic studies using radiolabeled DEHP by gavage in pregnant and nonpregnant female Wistar rats and CD-1 mice appeared in unpublished reports sponsored by the European Council for Plasticizers and Intermediates [193 – 197]. Determinations were made after single oral doses of 200 or 1000 mg/kg b.w. and after five daily doses at these levels. Results indicated rapid absorption, linearity of peak ra-

Figure 4. DEHP metabolism. The key metabolites are circled. (From Koch et al. [188], used with kind permission of Springer Science and Business Media and Prof. Dr. J. Angerer.)

diolabel plasma levels, and the area under the curve (AUC) with dose in both species irrespective of the pregnancy status. A rapid increase and biphasic radiolabel blood curve was noted in all mice but not in rats. This probably mirrors enterohepatic cycling of conjugates, e.g., glucuronides, which are formed in mice but not in rats. The plasma half-life times ranged between 7.1 and 10.3 h at the low dose and between 5.5 and 13.5 h at the high dose. The findings were confirmed when radiolabeled DEHP was given after five preceding doses. MEHP dominated DEHP in blood both at the low and the high dose level, as was seen from the AUC in rats (by a factor of 1.5–2) and mice (factor of ca. 2.5–3.5). In both species peak blood concentrations of DEHP and MEHP were comparable at the low dose (30–40 nmol/g); at the high dose peak MEHP concentration was approximately twice as high as that of DEHP. In rats, MEHP metabolites were ca. 10 % compared to the MEHP peak concentration and AUC. The MEHP metabolites were not detectable in mouse blood.

Species differences in metabolism between rats and mice were also noted by the urinary and fecal excretion pattern in a study using repeated

doses (10 doses, each 200 and 1000 mg/kg). In rats, the ω-1-oxidation metabolites, 5-OH- and 5-oxo-MEHP, accounted for 65 % compared to 35 % ω-oxidation metabolites, both in nonpregnant and pregnant rats, and at both dose levels. Excretion of metabolites occurred almost exclusively in urine. Unchanged DEHP and MEHP were excreted in comparable amounts: ca. 10 % of the administered dose each, and almost exclusively in the feces.

In mice, DEHP was also excreted exclusively in feces (6–10 % of the dose), whereas MEHP (15–25 % of the dose) was excreted 2/3 in feces and 1/3 in urine. Thus, much larger amounts of DEHP and MEHP were excreted in mice than in rats. The majority of the MEHP metabolites was excreted in urine (86 %; feces 14 %). ω-1-oxidation metabolites tended to decrease during the treatment (from 63 to 55 %) parallel to an increase in ω-oxidation (from 37 to 45 %) [193 – 197].

From these metabolism studies [193 – 197] with DEHP in pregnant and nonpregnant rats and mice it can be concluded that:

- DEHP and its metabolites are rapidly absorbed in both species as DEHP, MEHP, and MEHP-derived metabolites.
- The systemic exposure to MEHP is higher in pregnant mice than in pregnant rats, but DEHP exposure is equivalent.
- Metabolites from ω-1- (metabolites VI and IX, i.e. 5-OH- and 5-oxo-MEHP) and ω-oxidation pathways are excreted at higher levels in rats than in mice, but the subsequent β-oxidation of metabolite V (6-carboxy-MEHP) to form metabolite I (2-ethyl-4-carboxybutyl phthalate) is more active in mice than in rats.
- Repeated DEHP administration induced a modification of the metabolic pathway:
  - a decrease of DEHP excretion in nonpregnant and pregnant rats and in pregnant mice and an increase in nonpregnant mice
  - an increase of MEHP excretion in pregnant mice
  - an increase of ω-1-oxidation in rats and a decrease in mice
  - an increase of β-oxidation in pregnant mice at the high dose level.

An unpublished 65-week oral-dose toxicity study of DEHP in marmosets [198, 199] described pharmacokinetics and organ distribution following single oral doses of 100 and 2500 mg/kg DEHP to animals aged 3 and 18 months; a third group was treated at 18 months after a 65-week pretreatment with unlabeled DEHP. Ring-labeled ^{14}C-DEHP was used to determine radiolabel levels in blood (at 1, 2, 4, 8, 12, 24, 48, 72, 120, and 168 h after dosing) and in excreta. Organ distribution including male and female reproductive organs was examined 2 h after a second dosing, at least two weeks after the first treatment. Peak blood levels were reached within 1 or 2 h after dosing. Plasma half-life times of the radiolabel ranged between 2.7 and 8 h. The organ/plasma ratio was generally 0.2 to 0.4. The authors called particular attention to the small amounts of label distributed to the testes compared to rodents, in which large amounts of MEHP are distributed to the testes. Pretreatment for 65 weeks did not alter the distribution [198, 199].

No difference was seen when comparing blood concentration time courses of pregnant and nonpregnant rats and marmosets, respectively, receiving single or repeated doses of 30, 500, and 1000 mg DEHP per kg body weight. In both groups of rats MEHP AUCs were about two orders of magnitude higher than those of DEHP. Maximum MEHP blood levels were reached at 0.5, 2, and 4 h in animals receiving 30, 500, and 1000 mg/kg, respectively. The authors concluded that kinetics were linear for DEHP but saturated for MEHP, based on increased time to reach maximum blood levels [200].

The blood concentration time courses of pregnant and nonpregnant marmosets were similar except that the values of MEHP were lower in the high-dose pregnant group than in the nonpregnant group. Generally, the AUC of MEHP was ca. 10- to 20-fold higher than that of DEHP.

Comparison of species revealed that the AUCs of DEHP were similar in both species, while those of MEHP were 10-fold higher in rats than in marmosets [200].

The above confirms earlier studies in which rats dosed with 2000 mg kg^{-1} d^{-1} of DEHP for 14 d by gavage eliminated (on day 13) 56.2 % of the administered daily dose in the urine, and 58.7 % in the feces. The peak blood level on day 14 was 368 μg equivalents of DEHP per gram blood. In a parallel marmoset study the same dose regimen led to only 13 μg equivalents of DEHP per gram blood. Tissue levels were also

Table 6. Urinary metabolite excretion in a human 24 h after ingestion of DEHP, % of dose

Metabolite	Estimated elimination $t_{1/2}$, h	DEHP dose, μg/kg		
		4.7	28.7	650
MEHP	5	6.26	4.3	7.3
5-OH-MEHP	10	23.1	22.7	24.1
5-oxo-MEHP	10	17.3	13.0	14.6
Mono(2-ethyl-5-carboyxypentyl) phthalate	12–15	15.5	19.4	20.7
Mono[2-(carboxy-methyl)hexyl] phthalate	24	3.7	5.2	3.8
Total percentage of DEHP dose		65.8	64.6	70.5

much lower in marmosets, and no peroxisome proliferation or testicular effects could be detected [201].

In humans, urinary excretion of metabolites is also considered to reflect exposure and absorption. Two volunteers, each ingesting 30 mg of DEHP, excreted 11 and 15 % of the dose in the urine within 24 h. Four daily doses of 10 mg lead to a urinary recovery rate of 15–25 % [202].

One volunteer ingesting deuterium-labeled DEHP (48 mg, 0.64 mg/kg) excreted 47 % of the dose within 2 d as MEHP (7.34 %), 5-OH-MEHP (24.7 %), and 5-oxo-MEHP (14.9 %). Peak level of MEHP in urine occurred 2 h after dosing; the maximum urinary concentrations of the MEHP oxidation products occurred after 4 h. Serum levels of MEHP were higher than those of its oxidation products at all times, consistent with the more rapid elimination of polar metabolites. The estimated serum elimination half-life of all three metabolites was < 2 h [203].

The proportions of ω-1- and ω-oxidation were investigated in the 24-h urine of one volunteer ingesting three different doses (4.7, 28.7, and 650 μg/kg) of deuterium-labeled DEHP (Table 6). The ω-oxidation metabolites were mono(2-ethyl-5-carboyxypentyl) phthalate and mono[2-(carboxymethyl)hexyl] phthalate. The results indicate that excreted MEHP alone does not properly reflect the exposure because ω-1- and ω-oxidation contribute significant and varying proportions of the entire metabolism. The authors argued that serum MEHP level is not a useful marker for DEHP exposure due to its short half-life. However, they stated that serum levels were of the same orders of magnitude despite the fact that the human dose was 50–1000 times lower than in animal studies [378].

There are species differences in Phase-II metabolism between rats and mice (see above) and primates. After intravenous administration of DEHP to the African green monkey, 80 % of the urinary metabolites were excreted as glucuronide conjugates, in contrast to rats, which did not excrete conjugates in the urine [204]. In mice receiving 200 mg/kg, high proportions of the urinary MEHP (58 %) and MEHP-derived metabolites (49 %) were excreted as glucuronide conjugates [196]. This indicates that species differences in the rate of glucuronidation occur and may cause considerable variations in biological half-lives and tissue levels. As a consequence, the higher glucuronidation (detoxification) rate of the metabolites in primates may contribute to the observed lower MEHP peak concentrations and AUCs in marmosets compared to rats [198 – 200] and the higher resistance to DEHP-induced toxicity.

6.2.5.2. Acute Toxicity

Having entered the organism, one of the two ester bonds of phthalic diesters is cleaved and the alcohol is released [184, 185, 187, 202, 205]. Toxicological effects may result from the phthalic acid monoester and its sequel products and/or from the alcohol. In some cases (e.g., dimethoxyethyl phthalate) the impact of the alcohol is of greater importance [206 – 208]. The acute toxicity of diallyl phthalate is relatively high (LD_{50}, rat, oral: 800–1700 mg/kg) and it is irritating [215, 216], whereas most phthalates show very low acute toxicity. Acute oral toxicity in the rat and in the rabbit is summarized in Table 7.

Table 7. Acute toxicity of phthalate esters [209]

Phthalate ester	LD_{50} (rat, oral), mg/kg	LD_{50} (rabbit, dermal), mg/kg
Diallyl phthalate	≈ 1 500	
Dimethyl phthalate	> 5 000	> 12 000
Diethyl phthalate	> 9 000	> 20 000
Dibutyl phthalate	> 8 000	> 20 000
Diisobutyl phthalate	> 15 000	> 10 000
Diethylhexyl phthalate	> 30 000	> 24 500
Diisononyl phthalate	> 10 000	> 3 100
Diisodecyl phthalate	> 20 000	> 3 600
Diundecyl phthalate	> 15 800	> 7 900

6.2.5.3. Irritation and Sensitizing Potential

As a rule, most phthalates do not cause significant irritation [210 – 212] or sensitization of the skin [213, 214]. Diallyl phthalate [215, 216], however, may exert a weak irritating potential. Earlier reports of respiratory sensitizations appear to be related to contamination of the esters with phthalic anhydride and maleic anhydride.

6.2.5.4. Repeated DEHP Dosing

Effects in rodents on liver, kidneys, and testes were seen, as well as increased incidences of tumors in liver and testes (Section 6.2.5.6) and toxicity to reproduction (Section 6.2.5.7). Subacute and chronic effects as well as reproductive effects depend to some extent on chain length and structure of the alcohol moiety. Thus, a differentiation between short-, medium-, and long-chain esters appears to be justified (Section 6.2.5.8). Generally, the effects of phthalates are due to the monoester and metabolites derived therefrom, rather than the liberated alcohol and its metabolites. Exceptions to this rule are the more toxic allyl alcohol and the teratogenic methoxyethanol. 2-Ethylhexanol leads to 2-ethanoic acid, which is known to have a potential for teratogenicity. However, this is insufficient to explain the teratogenic effects seen with DEHP.

DEHP and several other phthalates act on the liver lipid metabolism in a qualitatively similar manner to a group of structurally unrelated compounds which are used or investigated as hypolipidemic drugs to reduce serum cholesterol and triglycerides. Increased enzyme activities involved in mitochondrial and peroxisomal fatty acid β- and ω-oxidation appear to be early effects of DEHP [217 – 219]. Initially, short transient inhibition of β-oxidation and lipid accumulation may occur, but subsequently can be overcome [220 – 222]. In rodents, but not in primates, the numbers and volumes of peroxisomes increase, and the liver undergoes a short period of DNA replication and cellular proliferation with a maximal mitogenic response after 24 h [223 – 226]. This results in a dose-related increase in liver weight which may double [224 – 231]. Plasma cholesterol values decrease in the same way as is observed with hypolipidemic drugs.

A study in Sprague–Dawley rats reports a continuous increase of peroxisomal enzyme activities upon prolonged treatment over two years [232]. In Fischer rats, increased peroxisomal enzyme activity was still present after two years, but not hepatomegaly or cellular proliferation [233]. 25 mg/kg of DEHP appears to be the no-effect level for the increase of peroxisome-related enzyme activity [228]. The no-effect levels for DINP and DIDP are somewhat higher; DBP is much less active [234].

Peroxisome proliferation and liver weight increase occurred in mice receiving DEHP in the diet (>1000 mg/kg, 24 weeks), but not in mice which were deficient in PPARα (PPARα-knock-out mice) [235]. Peroxisome proliferator-activated receptors (PPAR) are physiologically thought to play a role in lipid homeostasis in that they induce the expression of enzymes involved in lipid metabolism (β-oxidation, cytochromes P450). The three different types that are known to exist [PPARα, -δ (or -β), and -γ] respond to endogenous (fatty acids, prostaglandins, leucotrienes) and exogenous ligands (peroxisome proliferators: fibrates, phthalate esters, phenoxy herbicides). The sequence of action is the initial formation of a proliferator–receptor complex which becomes a transcription factor after association with the 9-*cis*-retinoic acid receptor [236, 237]. The transcription factor stimulates the expression of genes having specific promoter regions (peroxisome proliferator responsive elements, PPRE). The promoter regions are identical for all types of PPARs; differences in the enzyme induction pattern and intensity result from differences in the vicinity of the promoter region, cofactors, and the ligand itself, which, like

DEHP, may have overlapping affinity to all three types of PPAR [238, 239].

In rodent liver, PPARα mediates an increase of cell proliferation, inhibition of apoptosis, and increased expression of peroxisomal, mitochondrial, and microsomal enzymes [231, 240 – 242]. Under physiological conditions PPARγ is equally involved in the growth regulation of fat cells and epithelial cells of diverse organs [239], but its role in processes stimulating and inhibiting tumor growth are not yet fully understood [243]. PPARδ is also involved in cell cycle regulation and conversion of colon mucosa cells into carcinoma cells [243, 244].

The concentration of PPARs is high in rodents but low in primates including humans. In marmosets receiving 100, 500, and 2500 mg kg^{-1} d^{-1} DEHP for 13 weeks (oral, 91 consecutive days) peroxisome proliferation was not detected, neither by morphology nor by biochemistry, except for minor changes indicative of induction of some enzyme activities (increase in P450 and microsomal protein content) in all males and in females at the intermediate and high dose levels. The number of peroxisomes per cell was not affected. Only the mean volume of peroxisomes showed a slight increase (1.3–1.4-fold) at 500 and 2500 mg/kg b.w. Gross pathology, organ weights, histopathology, and electron microscopy did not show any substance-related findings in any of the treated groups. Especially the liver, pancreas, and testes or testicular parameters (Sertoli cells, Leydig cells, spermatogonia, spermatids, spermatozoa) were not affected. The NOAEL for systemic toxicity was 500 mg kg^{-1} d^{-1} in marmosets [245].

On the other hand, it was pointed out that DEHP can affect multiple signalling pathways by transcriptional activation of PPAR-regulated genes (suppression of apoptosis, protooncogene expression) and can induce biological effects (morphological cell transformation, decreased levels of gap junction intercellular communication) in several tissues independent of peroxisome proliferation and receptor binding [246].

Effects in kidneys, including changes in weight (both increase and decrease), function, and histopathology, were seen in several rodent studies (rat, oral, 2.1 mg kg^{-1}, 3 times per week, for 3–12 months; cystic changes and decreased creatinine clearance [247]; Fischer 344 rat, oral, $\geq$ 147 mg kg^{-1} d^{-1}, 104 weeks; increased weight, chronic nephropathy [248]; mouse, $\geq$ 99 mg kg^{-1} d^{-1}, 104 weeks; decreased weight, chronic nephropathy [249, 250] but not in primates [245].

6.2.5.5. Genotoxicity and Mutagenicity

DEHP and its metabolites have shown little if any genotoxic activity in a wide variety of short-term tests [251 – 257]. A few in vitro experiments on DEHP and MEHP were weakly positive and probably related to the cytotoxicity of MEHP [258 – 261]. The metabolites 5-OH- and 5-oxo-MEHP and mono(5-carboxyl-2-ethylpentyl) phthalate were also negative in the Ames test [262]. Positive results were seen with MEHP (39 μg/mL) in the Comet assay for DNA single-strand breaks using human leucocytes in the absence of metabolic activation [263]. Chromosomal aberration was seen with MEHP ($\geq$ 3.9 μg/mL) in Syrian hamster embryo cells [264].

Two dominant lethal studies [265, 266] using very high doses and exposure routes of little relevance (subcutaneous, intraperitoneal) showed positive results in vivo. However, the effects were of borderline significance and appear to reflect testicular toxicity rather than true genotoxicity. After oral administration of DEHP and MEHP, no dominant lethal effects were observed [267, 268].

DEHP has been shown not to react covalently with rat liver DNA after gavage administration following a 3-week prefeeding period [269]. When high doses of DEHP, known to cause peroxisomal proliferation, were repeatedly administered, an increase of 8-hydroxyguanosine in the DNA was found in the rodent liver but not in the kidney. This could reflect an oxidative DNA alteration [270], which, e.g., is also observed in rats fed on a choline-free diet [271], and other conditions of oxidative stress [272], but a second study on the same end point using more animals of the same strain, route, and dose (Fischer 344 rats, 12 000 mg DEHP per kg feed) but shorter duration (11 and 22 weeks, 6 rats per group) was negative [273]. Determination of 8-hydroxydeoxyguanosine in the DNA is very difficult to perform. In conclusion, there is no evidence that DEHP is genotoxic; the few positive results are contradictory or could result from cytotoxicity [274].

Other phthalates so far investigated showed similarly negative genotoxicity test results in most of the experiments [213, 227, 260].

6.2.5.6. Carcinogenicity

DEHP is again the phthalate ester most thoroughly investigated. Earlier chronic toxicity studies of DEHP showed no tumors in Wistar or Sherman rats over two-year periods at dietary levels of 4000 and 5000 ppm [275, 276]. Sprague-Dawley rats did not respond with liver tumors or preneoplastic lesions when fed with doses of 200, 2000, and 20000 ppm for 2 years; a continuous and sustained dose-and time-dependent peroxisomal proliferation was observed [232]. Due to the low animal numbers, all these studies are of limited value in assessing the carcinogenicity risk.

In more recent long-term rat and mouse feeding studies, increased incidences of liver tumors were seen. For example, increased incidences of hepatocellular carcinoma, adenoma, and preneoplastic foci were seen in Fischer 344 rats with 50 animals per dose group and sex, exposed to 6000 and 12000 ppm DEHP in the diet, and in B6C3F1 mice with 3000 and 6000 ppm [232]. The actual uptake from the feed was estimated to be 320–770 mg kg^{-1} d^{-1} in rats, depending on dose, sex, and food consumption, and 600–1800 mg kg^{-1} d^{-1} in mice [277]. A clear dose-dependent increase in the incidence of hepatocellular adenomas was noted in male/female rats fed 6000 and 12 000 ppm (322/394 and 674/774 mg kg^{-1} d^{-1}, respectively), and in male/female mice fed 3000 and 6000 ppm (672/799 and 1325/1821 mg kg^{-1} d^{-1}, respectively) for two years [278 – 280]. With a dose of 3000 mg kg^{-1} d^{-1}, 78.5 % of the treated rats developed liver tumors and 29 % pancreatic islet cell adenomas [281].

The relationship between hepatic peroxisome proliferation, cell proliferation, and carcinogenicity has been evaluated in chronic studies of DEHP in rats and mice [248 – 250]. Animals were fed a diet containing DEHP for 104 weeks; additional groups treated for only 78 weeks were subsequently placed on a DEHP-free diet for 26 weeks to examine reversibility of the effects. In rats, relative liver weight was significantly increased at 147 mg kg^{-1} d^{-1}, and this correlated with increased activity of palmitoyl CoA oxidase, a peroxisomal enzyme marker. Treatment with DEHP resulted in hepatocellular adenomas and carcinomas at weeks 78 and 104; in general, the incidence of tumors at week 78 was low except for the high-dose group. Cessation of treatment resulted in a one-third to one-half decrease in the incidence of total neoplasia relative to the groups treated for 104 weeks and in a reduction in liver weight and palmitoyl CoA oxidase activity. The increased incidence of hepatic tumors was significant at the 147 mg kg^{-1} d^{-1} dose level and higher in rats [248, 249].

Similar findings were reported in B6C3F1 mice. Cessation of treatment in mice resulted in a 50 % decrease in the incidence of total neoplasia in males relative to groups treated for 104 weeks, but the incidence in females decreased only slightly. The increased incidence in hepatocellular tumors achieved statistical significance at dose levels of 292 mg kg^{-1} d^{-1} DEHP [249, 250].

The role of peroxisome proliferation was further elucidated in an experiment with PPARα-null and wild-type [PPARα(+/+)] mice that were fed 0.1 % Wy-14,643, a model peroxisome proliferator. After 11 months of feeding 100 % of the wild-type animals had multiple hepatocellular neoplasms, including carcinomas and adenomas, while the PPARα(−/−) mice were unaffected [282].

Leydig cell tumors occurred in high incidences of 90–95 % in untreated F-344 rats and in animals at intermediate DEHP dose levels. The incidence was less than one-third in the high-dose groups [248, 249, 278, 280]. High incidences of this tumor are specific for this strain [283].

Similar results at comparable dose ranges (1.2–2.0 % in the diet) were obtained in consecutive studies with DEHP in smaller collectives of Fischer rats [230, 233, 284, 285] and in bioassays with two different forms of diisononyl phthalate and with a phthalate of a mixture of heptanols, nonanols, and undecanols (C_7–C_{11} fraction) [210, 286]. Other investigators [287] employing lower dose levels (up to 6000 ppm) did not find a statistically significant increase of liver tumors with a diisononyl phthalate. Under these conditions (6000 ppm over two years) the material did not exhibit peroxisome proliferation at the end of the 2-year observation pe-

riod. Different forms of diisononyl phthalates and related materials may exhibit slightly different profiles in relation to their structure and the type of branching and molecular shape.

Butyl benzyl phthalate, which is not a significant peroxisome proliferator, caused some mononuclear cell leukemia in Fischer rats at 1.2 % in the diet, but no liver tumors [210, 288].

Diallyl phthalate, similarly, did not cause liver tumors, but necrotic and fibrotic lesions of the liver and bile duct hyperplasia in rats, and gastric inflammation and hyperplasia in mice were observed. These effects were probably mediated via release of allyl alcohol. The doses in this study were 100 and 300 mg/kg in rats, and 50 and 150 mg/kg in mice [171].

In hamsters, inhalation of atmospheres saturated with DEHP vapor (ca. 15 mg/m^3; ca. 7–10 mg/kg) for two years or intraperitoneal injection up to a total dose of 54 g/kg, administered by weekly injections, did not increase the numbers of tumors [251]. Similarly, feeding of comparably low levels (300 and 1000 ppm) of DEHP did not lead to liver tumors [284].

Initiation/Promotion Experiments. No initiating activity was found with DEHP after single oral administration of 10 g/kg or after 12 weeks feeding of 1.2 %, followed by 0.05 % feeding of phenobarbital as promoter [289]. Generally, peroxisome proliferators have been recognized as a group of epigenetic rodent liver carcinogens which widely differ in their carcinogenic activity [290, 291]. Tumor-promoting activity of DEHP was investigated with several experimental procedures. The results were either negative or weak [292 – 296]; in some regimens antipromoting activities were also recorded [295, 297, 298]. There is evidence that peroxisome proliferators exert significant promoting effects only late in the rodent's life [299]. Di-*n*-octyl phthalate, which is not a peroxisome proliferator, was shown to be a liver tumor promoter [300], probably due to lipid accumulation and hepatomegaly [201].

There are several hypotheses on the mechanism of action. The most important and most complex seem to be the receptor-mediated mechanisms (Section 6.2.5.4), which are also associated with liver weight increase and replicative DNA synthesis [225]. Some authors focused on reduced expression of growth factor receptors [292, 301, 303]. Another hypothesis is that oxidative stress plays a role. Increased intracellular H_2O_2 and reactive O_2 species released from the peroxisomes [290, 304 – 306] may cause continuous accumulation of 8-hydroxydeoxyguanosine in the DNA [270]. Leakage of H_2O_2 from peroxisomes is reflected by increases in oxidized glutathione in the bile [291]. Conjugated dienes and accumulation of lipofuscin pigments in lysosomes were also observed and indicate oxidative stress to the cell [224, 277, 291, 307]. It is, however, not clear whether oxidative stress is cause or consequence in the course of phthalate ester tumorigenesis.

No direct genetic activity is observed with phthalate esters (see also Section 6.2.5.5). This also applies to hypolipidemic drugs, even if they stimulate peroxisomes at very low doses and are strongly carcinogenic in rats and mice [291]. These rodent liver tumors are therefore regarded as epigenetic and a sequel of the liver effects. The present knowledge allows the assumption that threshold levels for these early-appearing liver effects also reflect a threshold for the appearance of liver tumors in rodents. In addition, phthalate esters do not cause peroxisome proliferation in nonrodents including primates.

6.2.5.7. Reproductive Toxicity

Testicular Toxicity. Phthalate esters of medium and longer chain length (C_3–C_6, DEHP) cause testicular damage [290, 308 – 322]. The lesion is characterized by an initial effect on Sertoli cells [323, 324] leading to the exfoliation of spermatocytes and spermatids with atrophic degeneration of seminiferous tubules containing cytoplasmic remnants of Sertoli cells and spermatogonia [323, 325].

Minimal vacuolization of Sertoli cells was reported to occur in rats receiving 38 mg kg^{-1} d^{-1} DEHP for 13 weeks; at a 10-fold higher dose level, 375 mg kg^{-1} d^{-1}, mild vacuolization and testicular atrophy were noted. The authors derived a no-adverse-effect level (NOAEL) of 3.7 mg kg^{-1} d^{-1}. However, because the same effects were seen in control animals in a second experiment of the same study[333], the true NOAEL should be considered to be 37.6 mg kg^{-1} d^{-1}. Germ cell detachment may also be observed in vitro with MEHP [323, 334] but

Table 8. Effects of DEHP on male fertility

Species, strain	Dose, mg kg^{-1} d^{-1} (duration)	Effect (dose, mg kg^{-1} d^{-1})	Ref.
Rat, SD	0, 143, 737 (17 weeks)	testes weight ↓ (737)	[326]
Rat, F-344	0, 322, 674 (103 weeks)	atrophy of seminiferous tubules (674)	[280]
Rat, F-344	0, 330, 1000, 3000 (13 d)	slight atrophy of testes (1000)	[327]
Rat, F-344	0, 320, 1250, 5000, 20000 (60 d)	testes weight ↓, testosterone↓, LH ↑, FSH ↑ (284)	[328]
Rat, SD	0, 10, 100, 1000, 2000 (5 d)	palmitoyl CoA oxidase ↑ (10), liver weight ↑ (100); testes weight ↓, no. Sertoli cells ↓, spermatocytes ↓, spermatids ↓, testicular zinc ↓ (1000)	[324, 329]
Rat, Wistar	0, 50, 100, 250, 500 (30 d)	slight testes weight ↓, change of testicular enzymes (50); significant testes weight ↓ (100); histopathological changes, testes (250)	[330]
Rat, F-344	0, 6, 29, 147, 789 (104 wk)	bilateral aspermatogenesis in aged rats (29); testes weight ↓, bilateral aspermatogenesis (789)	[248]
Rat, Wistar	0, 113, 340, 1088	advanced atrophy of seminiferous tubules, aspermia in epididymes (1088)	[331]
Rat, SD	0, 0.12, 0.78, 2.4, 7.9, 23, 77, 592, 775 (unspecified weeks)	sperm density ↓; male accessory organ weights ↓; atrophy of seminiferous tubules; sloughed epithelial cells in epididymis (592)	[332]
Marmosets	0, 100, 500, 2500 (91 d)	testes and testicular parameters (Sertoli cells, Leydig cells, spermatogonia, spermatids, spermatozoa) not affected (2500)	[199]

not with 2-ethylhexanol [335]. Further hormonal sequels of the testicular atrophy are decreases of serum testosterone and increases of serum FSH (follicle stimulating hormones) and LH (luteinizing hormones) [328]. Some of the early and late effects and the respective dose levels following administration of DEHP are summarized in Table 8. Extensive studies have been conducted on the effects on Sertoli and Leydig cells, as well as testosterone and sex hormone regulation in male rodents. The absence of any effect in marmosets [199] indicates that marked physiological and endocrine differences exist between rodents and primates regarding Sertoli cell and Leydig cell physiology and susceptibility, and sex hormone regulation. Rodent Leydig cells are regarded as more sensitive than human Leydig cells [283]. Atrophy of the seminiferous tubules is generally seen in rodents at doses >250 mg kg^{-1} d^{-1}. The exact mechanism is still unknown [209].

Early functional effects, e.g., reduced sperm counts, may be seen at lower dose levels, whereas in acute studies relatively high (> 250 mg/kg) oral doses are required to induce visible testicular damage. In experiments of longer duration the effective levels are considerably lower. Serum testosterone [328] and male fertility in continuous breeding protocols appear to be sensitive parameters. The no-effect levels (NOAEL) are in the range 25–50 mg kg^{-1} d^{-1}. A dose of 1250 ppm (70 mg kg^{-1} d^{-1}) in the diet of rats decreased serum testosterone within 60 d [328]. This is a dose range which caused malformations in a mouse teratology study [304, 336].

Reversal of testicular effects is slow and incomplete. After administration of 2000 mg kg^{-1} d^{-1} DEHP for two weeks to rats, only slight reversal of the testicular lesions occurred after 45 d [318]. Incomplete reversal was also observed after 60-d feeding of 20 000 ppm of DEHP in the diet of rats and a 70-d postobservation period [328]. The effects are age- and, to some extent, species-related [321]. Young rats (4-weeks-old) appear to be more susceptible (lower doses, shorter duration required) than adult rats. This age-dependent susceptibility has been successfully modeled with MEHP in primary testicular cultures from rats of varying age [334].

As to species differences, DEHP can also induce testicular atrophy in mice [315, 337], guinea pigs [325], ferrets [338], and hamsters [229]. Marmosets appear to be more resistant; oral doses of DEHP (2000 mg/kg for 2 weeks [201]; 2500 mg kg^{-1} d^{-1} for 91 consecutive days [199]) caused no testicular toxicity. A lower intestinal resorption and higher rate of excretion may contribute to these findings [218].

The mechanism of testicular toxicity is still unclear, but zinc is thought to play a role. Testicular zinc content is decreased while urinary zinc increases [308, 314, 319]. Detailed studies with di-*n*-pentyl phthalate [339] have not been able to indicate whether the changes in testicular zinc content are solely a secondary phenomenon. A zinc-supplemented diet partially protected rats from DEHP-induced testicular damage, whereas rats on a zinc-deficient diet were more sensitive [327]. Hypolipidemia and hepatomegaly appeared to occur independently of zinc supplementation. On the other hand, there is evidence that reduced testicular zinc content was probably a result of testicular toxicity after DEHP treatment rather than a mediator of DEHP toxicity [340].

Diethyl and di-*n*-octyl phthalate showed no adverse effects on fertility and the testes [337, 345]. Comparative studies using several mono- and di-esters were conducted in male Sprague-Dawley rats, orally treated for four weeks with phthalate diesters at 500 mg kg^{-1} d^{-1} or phthalate monoesters at 250 mg kg^{-1} d^{-1} [313]. Animals were evaluated for body weight, testicular and epididymal weights, epididymal sperm count, and sperm motion parameters. There were no significant effects of treatment on body or reproductive organ weight. The order of effects on sperm motility for the diesters was DEHP > DnOP > DEP > DUP > DIDP > BBP, and for the monoesters MBuP > MEP > MEHP (MBuP = monobutyl phthalate; MEP = monoethyl phthalate) [313].

The relevance of rodent data to humans is still under debate. The absence of testicular effects in monkeys even at 2500 mg kg^{-1} d^{-1} [199], and the failure to confirm vacuolization of Sertoli cells in rats [331, 332] are major factors in this discussion because the NOAEL of 3.7 mg kg^{-1} d^{-1} for vacuolization was used by several institutions during their evaluations and risk assessments [274, 342, 343].

Effects on Fertility and Development. There are two high-quality rat studies available which deserve a more detailed description.

In a two-generation reproductive study in Wistar rats DEHP was administered in feed at 0, 1000, 3000, and 9000 ppm, resulting in estimated intakes of 0, 113, 340, and 1088 mg kg^{-1} d^{-1} [331]. Cauda epididymal sperm were assessed for motility, morphology, and head count in F0 and F1 males at necropsy. Testicular sperm head count was also performed. Male pups were evaluated for the presence of nipples and areolas. Day and weight at vaginal opening and preputial separation were assessed in pups. F2 pups were also evaluated by functional observation battery and motor activity testing, and in a water-maze test of learning and memory.

The high-dose level (9000 ppm) was associated with a decrease in feed consumption and weight gain at several intervals during the study. F2 pups in the high-dose group were smaller and gained less weight from birth through the assessment of functional observation battery and water-maze testing. Grip strength was reduced in males and hind-limb splay was reduced in both sexes in the high-dose group. There were no other treatment-related findings in the functional observation battery or in the water maze. Differential ovarian follicle counts of F0 and F1 adults showed a deficit in growing follicles and corpora lutea in the high-dose group.

It was concluded that reproductive performance and fertility were affected at the 9000 ppm dose level (1088 mg kg^{-1} d^{-1}) with a NOAEL of 3000 ppm (340 mg kg^{-1} d^{-1}), and that developmental toxicity was noted at 3000 and 9000 ppm, with an increase in stillbirth, an increase in postnatal day (PND) 0–4 pup mortality, retardation of F2 pup body weight, altered male anogenital distance, and retained nipples/areolas. A delay in sexual maturation was also noted in F1 offspring at 9000 ppm. The NOAEL for developmental toxicity was considered by the study authors to be 1000 ppm, as was the NOAEL for systemic toxicity (113 mg kg^{-1} d^{-1}) [331].

In a multigeneration continuous-breeding study Sprague-Dawley rats were fed diets containing 1.5 (control group exposed to background DEHP levels), 10, 30, 100, 300, 1000, or 7500 ppm DEHP from the first day of the

study until the day of necropsy [302, 332]. Due to a lack of reproductive effects in the first litter produced, the study was repeated with two additional doses, 1.5 (control) and 10 000 ppm. Ranges of DEHP intake in the F0, F1, and F2 animals were estimated at 0.09–0.12, 0.47–0.78, 1.4–2.4, 4.8–7.9, 14–23, 46–77, 392–592, and 543–775 mg kg^{-1} d^{-1}. At about five weeks of age, F0 rats were fed the DEHP-containing diets for six weeks prior to mating and were then cohabitated for nine weeks. The first two litters delivered during the cohabitation period (F1a and F1b) were counted, weighed, assessed for anogenital distance, and then discarded. The third litter (F1c) was raised by the dam. Following weaning of pups, vaginal cytology was monitored in F0 females for 14 d. After completion of crossover studies described below, some of the F0 rats were necropsied. Sperm analyses were conducted, and organs were collected for histopathological evaluation. F1 pups were counted, weighed, and examined for anogenital distance and nipple retention during the lactation period. On PND 16, one female per litter was evaluated for vaginal opening, and a second was selected for F1 mating. One male per litter was selected for mating, and 4 or 5 males per litter were evaluated for testicular descent and preputial separation. At weaning on PND 21, pups were given diets containing the same DEHP concentrations as their parents. On PND 81, the F1 rats chosen for mating (17 per sex per group) were randomly assigned to breeding pairs (preferably nonsibling) and cohabited for nine weeks. The study conducted in F0 parents and F1 offspring was repeated in F1 parents and F2 offspring, except that no F3 offspring were mated. Selected F3c males were necropsied on PND 63–64 and selected females on PND 60–74.

During numerous time periods of the study and especially at necropsy, body weight gains were decreased in rats from the 7500 and 10 000 ppm groups. Dam body weights during delivery and lactation were decreased by 8–20 % in the F0 10 000 ppm group. Increases and decreases in feed intake were observed at most dose levels. In the F0 7500 and 10 000 ppm groups, feed intake was decreased during lactation. The liver was identified as a target of toxicity with increases in liver weight and hepatocellular hypertrophy observed at dose levels $\geq$ 1000 ppm. Changes in organ weights and lesions were also observed in the kidney at $\geq$ 7500 ppm and the adrenal gland at 10 000 ppm. The only reproductive effects observed in the F0 parents occurred at 10 000 ppm and included decreases in sperm counts and velocity, reductions in testis and epididymis weights, and increased numbers of rats with small testes. Histopathological findings associated with small testes included minimal to marked atrophy of seminiferous tubules characterized by loss of germ cells.

The lowest dose level producing dose-related effects in F1 offspring was 7500 ppm, and those effects included decreases in number of live pups per litter, reduced male anogenital distance, and delays in vaginal opening, preputial separation, and age at testicular descent. Additional effects noted in the F1 offspring from the 10 000 ppm group included decreased live pup weight at birth and during the lactation period and increased ratio of female anogenital distance to body weight. Fertility was compromised in the F1 rats from the 10 000 ppm group, which did not produce any viable litter. Other effects observed in F1 parents were similar to those observed in F0 parents but occurred at lower dose levels. Histopathological findings observed in all animals of the 7500 and 10 000 ppm groups were consistent with those observed in the F0 generation and included minimal-to-marked seminiferous tubule atrophy and occasional sperm-release failure. Additional reproductive effects observed in F1 rats were reduced sperm counts at 7500 ppm and higher and increased uterus and ovary weights at 10 000 ppm.

In the F2 pups, delays in preputial separation and testicular descent occurred at each dose level. Other effects occurring in F2 pups of the 7500 ppm group included delayed vaginal opening and reductions in live pup weight at birth and during the lactation period, male anogenital distance, and survival during the lactation period.

In the F3 offspring, seminiferous tubule atrophy was observed in 10/10 males from the 7500 ppm group. All other reproductive effects in F2 adults occurred at 7500 ppm and included decreases in pregnancy index, the number of litters per pair, male reproductive organ weights, sperm counts, and sperm motility. The F3 generation was the only generation in which there was an increase in males with nipples. Other F3 effects included reduced sperm counts and weights of

dorsolateral prostate, testis, and epididymis at 7500 ppm.

The study authors discussed the relevancy of small male reproductive organ sizes observed in both F1 and F2 rats of the 300 ppm groups. They noted that although incidences were low, the effects were consistent with phthalate-induced toxicity. The incidence of small testes and epididymides exceeded historical control data from the laboratory. Therefore, the effects were considered as potentially treatment-related. However, the study authors concluded that the overall significance of the effects cannot be determined due to lack of histopathological data and lack of adverse reproductive effects at 300 and 1000 ppm. Using crossover studies, the male was identified as the sex in which adverse fertility effects occurred.

In conclusion, DEHP was clearly a reproductive and developmental toxicant at 7500 and 10 000 ppm based on changes in fertility and pregnancy indices, litter data, sperm parameters, sexual development, and/or histopathological changes in testes. Intake at 7500 ppm was estimated at 392–592 mg kg^{-1} d^{-1}, and that at 10 000 ppm at 543–775 mg kg^{-1} d^{-1}. Based on the incidence of testicular abnormalities, the CERHR Expert Panel considered 300 ppm to be an effect level, giving a NOAEL of 100 ppm, about 3–5 mg kg^{-1} d^{-1} [344]. Sertoli cell vacuolation, which was the end point driving the LOAEL in the original CERHR Expert Panel evaluation of DEHP [342, 344], was not increased by DEHP treatment in this study [302, 332].

In CD-1 mice exposed to 0.3 % DEHP in the feed in a continuous breeding protocol, complete suppression of fertility at the highest dose ($\approx$ 430 mg kg^{-1} d^{-1}) was observed. At 0.1 % a significant reduction in fertility was induced. No effects were seen at 0.01 % ($\approx$ 20 mg kg^{-1} d^{-1}). A cross-over mating employing treated males and females from the 0.3 % groups indicated significant effects on both the male and female reproductive function [304, 345].

DBP exposure in mice resulted in a reduction in the number of litters at 1.0 % in the diet, but not at 0.3 %. Females were more affected than males [345]. Di-*n*-hexyl phthalate affected both sexes of mice in a dose-related fashion [345] at 0.3, 0.6, and 1.2 %. Di-*n*-pentyl phthalate completely inhibited fertility at 1.25 % and 2.5 %. Di-*n*-propyl phthalate caused complete inhibition at 5.0 % and reduced fertility at 0.5 % and 2.5 %. Di-*n*-pentyl phthalate was more toxic to males, and di-*n*-propyl phthalate more toxic to females [337]. Diethyl and di-*n*-octyl phthalate showed no adverse effects on fertility and the testes [337, 345].

An abnormal sexual development was seen in male rats with in utero and lactational exposure to DEHP (oral gavage, dose levels 0, 375, 759, or 1500 mg kg^{-1} d^{-1}, dosing during gestational day 3 through postnatal day 21) [346]. Dose-related effects on male offspring included reduced anogenital distance, areola and nipple retention, undescended testes, and incomplete preputial separation. Testis, epididymis, glans penis, prostrate and seminal vesicle weights were reduced at postnatal days 21, 63, and/or 105–112. Further increased incidences of prostrate and seminal vesicle agenesis, reduced sperm counts, and testicular, epididymal and penile malformations were noted. The observation that many of the exposed males were sexually inactive was suggested to reflect an inhibition of the sexually dimorphic central nervous system development. DEHP was attributed an "anti-androgenic action" the anogenital distance reduction was only seen in male rats, together with the retention of areolas and nipples, whereas DEHP had no significant effect on vaginal opening or the first estrus. The exact mode of action is still unclear, but anti-androgenicity must not be confused with estrogenicity [346]. In an uterotrophic assay in ovariectomized female rats, DEHP (1000 mg kg^{-1} d^{-1} for 5 d) had no estrogen activity as it failed to change sex hormone levels or uterus estrogen receptor levels, or to increase uterus weight, and finally there was no difference compared to controls during histopathology in uterus [347, 348].

Prenatal Toxicity; Embryotoxicity; Teratogenicity. Embryotoxic and teratogenic effects of DEHP and DBP depend on species, dose, and route of administration. Mice are more sensitive than rats, and feeding appears to be more effective than gavage or inhalation.

In mice, DEHP and DBP caused teratogenicity after oral administration [337, 345, 349 – 353]: In CD-1 mice 0.1 and 0.15 % of DEHP in the diet produced both maternal and fetal toxicity [304, 352]. Malformations (eye and

tail defects, exencephaly, aortic and pulmonary arch defects, and skeletal defects) were observed at 0.05 % in the absence of maternal or fetal toxicity. No effects were reported at the lowest dietary level in this study (0.025 % DEHP, equivalent to ca. 35 mg kg^{-1} d^{-1}) [354].

DBP caused reduction of the numbers of litters and of live pups per litter at the 1.0 % level, but not at 0.3 % in a continuous breeding study [345]. In another feeding study in mice, with 1 % DBP in the diet, a slight increase in malformations (exencephaly and spina bifida) was observed [349, 350].

Butyl benzyl phthalate at 2 % in the diet of rats caused complete resorption of all litters (embryonic or fetal death), whereas 1 % and 0.5 % were without effect [190]. In another rat feeding study [355] 2 % of butyl benzyl phthalate in the diet did not lead to complete resorption of the litters; the number of malformations was greatly increased. In mice, malformations occurred, with a dose-dependent increase at 0.5 and 1.25 %. The maternal and developmental no-adverse-effect level was 0.1 % [355].

In rats, only embryotoxic effects were observed, with little indication of teratogenicity, even at dose levels that led to some maternal toxicity [331, 336]. Postimplantation loss was significantly increased in F0 and F1 dams at 1088 mg kg^{-1} d^{-1}, and viability of the F1 and F2 pups was reduced in the groups at 340 mg kg^{-1} d^{-1}. Genital organ malformations (hypospadia, cleft prepuce, small penis) were noted in only two high-dose F2 pups [331].

The number of fetuses with external, soft tissue, and skeletal malformations was increased in a Wistar rat study [0, 40, 200, 1000 mg kg^{-1} d^{-1}, exposure during gestational day (GD) 6–15]. Malformations were seen at the maternally toxic high-dose level, and were mainly confined to the tail, brain, urinary tract, gonads, vertebral column, and sternum [356].

Following exposure to DEHP in utero (GD 14 to PND 3, 750 mg kg^{-1} d^{-1}) malformations of reproductive organs were observed in 82 % of DEHP-treated males at necropsy. The types of malformations included permanent nipples, clefting of phallus and hypospadias, vaginal pouches, agenesis of prostate, seminal vesicles, or coagulating glands. Sperm production and sperm numbers were reported to be not affected by DEHP treatment, as was sexual behavior in adult rats, except that males with malformed penises were unable to achieve intromission. Testicular defects included hemorrhage, granuloma, fibrosis, reduced size or atrophy, and nondescent associated with abnormal gubernacula or ligaments. Dihydrotestosterone-dependent end points, i.e., reduced AGD and areolas, were affected [357]. Inhalation of DEHP aerosols up to 300 mg/m^3 did not cause embryotoxic or teratogenic effects [300].

As to the mechanism, zinc depletion and interference with sex hormone regulation have been discussed. Since DEHP in the diet might interfere with zinc resorption and metabolism the prenatal toxicity may partly be due to zinc depletion, which is known to cause teratogenic effects [358]. Dihydrotestosterone-dependent end points, i.e., reduced AGD and areolas, were affected by DEHP, BBP, and DINP, but not by DMP, DEP, and DOTP [357].

No teratogenicity or embryotoxicity was found with dimethyl [359] and diethyl phthalate [360] in rat feeding studies (0.25–5.0 % in the diet) or with dimethyl phthalate in rats after occlusive epicutaneous administration (0.5, 1.0 and 2.0 mL kg^{-1} d^{-1}; 2 h/d; gestation days 6–15) [361].

Di(methoxyethyl) phthalate is teratogenic due to the release of highly teratogenic methoxyethanol [206 – 208].

6.2.5.8. Effects of Phthalate Esters by Groups

Relations between structure and effects of phthalate esters seem to exist, and it appears to be justified to group them according to the structure of the alcohol moiety, i.e., linear chain length and structure (linear or branched).

Short-Chain Phthalate Esters (C_1–C_3). Dermal exposure to dimethyl phthalate in humans occurs widely due to its use in insect repellants; so far, no significant toxicological side effects were observed [213]. Dimethyl and diethyl phthalate are used in cosmetics at concentrations of < 10 % and are dermally resorbed. They are considered to be nonirritants, nonsensitizers, and nonphototoxic agents [213]. Feeding studies in rats and mice with diethyl phthalate caused liver weight increases at high doses

($\geq$ 0.5 % in the diet), but no testicular toxicity [308 – 310, 345]. Peroxisome proliferation is only marginal and requires high doses [223]. Developmental toxicity is regarded as insignificant [359 – 361].

Dimethoxyethyl phthalate has a teratogenic potential [206 – 208] due to the released methoxyethanol.

Diallyl phthalate is acutely relatively toxic (LD_{50}, rat, oral: 800–1700 mg/kg) and irritating [215, 216]. In a long-term bioassay with gavage administration there was no clear carcinogenic activity, but allyl alcohol-related toxicity was observed (see Section 6.2.5.6).

Medium-Chain Phthalate Esters (C_4–C_7). Di(2-ethylhexyl)phthalate (DEHP) is the substance examined most extensively, and countless publications on toxicological profile, biochemistry, and metabolism exist. Far fewer data have been generated on any other phthalate ester.

In rodents, but not in other species, hepatic alteration (peroxisome proliferation and hepatomegaly [210, 227, 228, 317]) is observed. The peroxisome proliferation is somewhat more pronounced in the group of longer chain phthalates, especially of the branched-chain type.

Branched-chain phthalates commonly share a potential to induce peroxisomes and hepatomegaly in livers of rats and mice at high doses. This was demonstrated with diethylhexyl phthalate (DEHP), diisononyl phthalate and diisodecyl phthalate. These materials may cause peroxisome proliferation and hepatomegaly in rodents (DEHP at doses exceeding 50 mg kg^{-1} d^{-1}) [201, 210, 223 – 230, 232, 234, 278]. In long-term feeding experiments, DEHP [362] and related phthalates [210] also led to an increase of liver tumors in rodents, mediated by receptor PPARα. This mechanism is specific to rodents and not relevant to humans. The role of peroxisome proliferator activated receptors (PPARs) is outlined in Section 6.2.5.4. Nonrodents and primates have no or very low levels of PPARs and do not show these liver effects [189, 201, 290, 363, 364]. Hence no carcinogenicity is expected for humans, though some uncertainty remains because there might be receptor-independent effects (see Section 6.3.2).

Apart from the liver, effects were also seen in kidneys and the thyroid gland. Chronic administration of $\geq$ 0.5 % of DEHP in the diet also led to kidney toxicity in rats and mice with organ weight increase, cystic changes, dysfunctions [365 – 368], and alterations in thyroids [366, 369], with a fall in plasma thyroxine levels associated with hyperactivity and changes of the thyroidal colloid spaces. Effects on the thyroid gland were also observed with other peroxisome proliferators [369].

The straight-chain analogues di-*n*-hexyl and di-*n*-octyl phthalate also show thyroid effects although they differ in terms of hepatic toxicity [226, 366]. Di-*n*-octyl phthalate causes a different type of renal toxicity than DEHP [370].

Medium-chain phthalate esters exhibit degenerative testicular effects upon repeated oral administration in mice, rats, and hamsters [308 – 320]. The testicular effects are also obtained with DEHP (C_8, branched) to a similar degree but are not observed with the linear longer chain di-*n*-octyl phthalate or with short-chain phthalates. Testicular effects were noted with DEHP after oral intake in rats and mice, [234, 309, 313, 317, 318, 321] but were lacking in monkeys [199]. Oral uptake of $>$ 50 mg kg^{-1} d^{-1} of DEHP also caused embryotoxic and teratogenic effects in mice [337, 345, 349 – 353]. In rats, some embryotoxicity was observed in feeding studies at maternally toxic levels [352], but not upon inhalation [300].

Dibutyl phthalate (DBP) also caused embryo toxicity and teratogenicity at a concentration of 1 % in the diet of ICR/ICL mice [315, 349, 350]. After a 6-month inhalation exposure of rats to 50 mg DBP/m^3 for 6 h per day, an accumulation of DBP in the brain and increase of brain weight were found; at 5 mg/m^3 these effects were marginal [371].

Butyl benzyl phthalate at 2.5 and 5.0 % in the feed caused testicular effects, enlargement of liver and kidneys and decrease of bone marrow cellularity and thyroid function in rats [372].

Longer Chain Phthalate Esters (C_8–C_{12}). Di-*n*-octyl phthalate did not exert testicular toxicity in vivo [337, 341, 345] nor significant peroxisome proliferation in the liver [362]. It was shown to be a liver tumor promoter in a rat feeding experiment [373], probably as a sequel of fat accumulation and hepatomegaly [226].

The straight-chain DEHP analogues di-*n*-hexyl and di-*n*-octyl phthalate also show thyroid effects although they differ in terms of hepatic

toxicity [366]. Di-*n*-octyl phthalate causes a different type of renal toxicity than DEHP [370].

The effects of a group of high molecular weight phthalate esters (HMWPEs) comprising C_7–C_{12} alkyl backbone esters (di-2-propylheptyl ester; bis(C_7–C_9) branched and linear alkyl esters; di-C_{11} branched and linear alkyl esters; di-C_{11} alkyl ester; bis(C_{11}–C_{14}) branched and linear alkyl esters, C_{13}-rich; di-C_{13} alkyl ester) have recently been assessed as a category of related chemicals in the course of the global OECD-ICCA-HPV program [374]

HMWPEs have a low order of acute toxicity by the inhalation, dermal, intraperitoneal, and oral routes of exposure. Chemicals of the HMWPE category are not irritating to the skin or eyes (only slight conjunctival irritation for di-C_{13} alkyl ester), nor are they skin sensitizers (maximization test or comparable, or Buehler method). Although some data for these end points are older, the weight of evidence is consistent.

The primary findings in the repeated-dose rat studies were in the liver and kidney and to a lesser degree in the thyroid. Effects on the liver are indicative of peroxisomal proliferation, including increased PCoA, liver weights, and liver hypertrophy, and are not relevant to humans. It has been shown that these effects are mediated through peroxisome proliferation activated receptor alpha (PPARα) and that levels of PPARα are much higher in rodents than humans. Thus, one would expect humans to be substantially less responsive than rodents to peroxisome-proliferating agents. Empirical evidence for this hypothesis has been provided by studies in primates, in which repeated administration of DINP had no effects on liver, kidney, or testicular parameters, including peroxisome proliferation. The kidney effects were a result of a dose-dependent α-2μ-globulin nephropathy. Such effects are sex- and species-specific to male rats and also are not relevant to humans. Thyroid effects are likely to be a compensatory effect associated with the peroxisomal proliferation in the liver. The results were consistent for all members of the category, with NOAELs ranging between 10 and 282 mg^{-1} kg d^{-1}. The 10 mg^{-1} kg d^{-1} value was delivered in an OECD 422 study in which rats were dosed for 45 d, and the effect observed at 50 mg^{-1} kg d^{-1} was increased liver weight. This is likely to be related to peroxisome proliferation. All the NOAELs are driven by liver and/or kidney effects.

HMWPE category members are nongenotoxic. All of them have been tested in the Ames reverse mutation assay using *Salmonella typhimurium* and all were nonmutagenic with or without metabolic activation. Similarly, a range of substances covering the majority of the carbon numbers in this category was found to be inactive in the mouse lymphoma tests. Additional testing of di-C_{13} phthalate ester showed that the test substance did not induce either structural chromosomal aberrations or polyploidy in Chinese hamster liver cells up to the limit concentration of 4.75 mg/mL, in the absence or presence of an exogenous metabolic activation system.

Although HMWPEs have not been tested for carcinogenic properties (i.e., chronic toxicity or bioassay studies), previous experience with a wide range of phthalates including di-*n*-octylphthalate and DINP suggests that high doses might produce liver changes in rodents via interaction with PPARα. However, these are considered to be not relevant to humans and not indicative of a potential human risk. Three chronic toxicity/carcinogenicity studies on DINP have been conducted: two in rats and one in the mouse. In the rat studies, the major findings were liver and kidney changes principally related to the induction of peroxisome proliferation. There was an increase in liver tumors in both male and female rats and also a small increase in kidney tumors in the male rats. Both of these tumors are considered to be rat-specific and without relevance to humans. In the mouse study, there were liver tumors as well, also the consequence of peroxisomal proliferation, but no tumors of other types. It should be noted that di-*n*-octyl PE was a liver tumor promoter in a rat feeding study [373], probably as a sequel of fat accumulation and hepatomegaly [226].

Although not all members of the category have been tested for reproductive toxicity (di-2-propylheptyl, PE, di-C_{11} PE, or di-C_{13} PE), there are data for the lower [bis(C_7–C_9) PE], intermediate [bis(C_9–C_{11}) PE], and higher (di-C_{13} PE) molecular weight representatives indicate no significant reproductive toxicity at doses up to 500 mg^{-1} kg d^{-1} (or 250 mg^{-1} kg d^{-1} di-C_{13} PE). Effects included transiently decreased body weights or slightly decreased ovary and epididymidal weights. These effects are minor

and are not directly related to reproductive toxicity. Furthermore, the category members bis(C_7–C_9) PE and bis(C_9–C_{11}) PE have been recently shown not to be associated with detectable reproductive effects and do not affect fertility, similarly to DINP and DIDP.

Data from the developmental toxicity tests for the HMWPE conducted in rats on di-2-propylheptyl, bis(C_7–C_9), bis(C_9–C_{11}), and di-C_{13} PEs, have shown minimal maternal toxicity at doses up to 1000 mg^{-1} kg d^{-1} (limit dose) or 250 mg^{-1} kg d^{-1} (di-C_{13} PE). Either no effects were produced or the effects were associated with decreased food consumption and body weight loss in dams. Only the di-2-propylheptyl PE showed maternal toxicity at the limit dose and associated effects of resorption, decreased litter size, or fetal survival associated with the above two symptoms of maternal toxicity. In the two-generation study on DIDP, a decrease in offspring survival, more marked in F2, was observed. In the di-C_{13} PE one-generation study (F1 generation) a decrease in survival indices was observed, leading to a NOAEL of 50 mg^{-1} kg d^{-1} for offspring rats, whereas NOAELs for parental rats were 250 mg^{-1} kg d^{-1}. These may be considered related to developmental effects. No such changes were seen in either generation of the separate studies on bis(C_7–C_9) and bis(C_9–C_{11}) PE; these results are consistent with those from DIDP studies. However, none of the HMWPEs tested produced developmental effects. Increased frequencies of developmental variants including dilated renal pelvis and supernumerary lumbar ribs were produced in the studies on bis(C_7–C_9) PE and bis(C_9–C_{11}) PE, but are common findings in rats. Although not all members of the HMWPE Category have been tested for developmental toxicity, there are data for the lower [di-2-propylheptyl and bis(C_9–C_{11}) PE], intermediate [bis(C_9–C_{11}) PE], and higher (di-C_{13}) molecular weight representatives. Like DINP and DIDP, they have shown no significant developmental toxicity. It is reasonable to conclude that other members of the category would behave similarly, as shown by the weight of evidence. Thus, it can be concluded that this category of HMWPE induces no biologically significant developmental effects in rodents.

In conclusion, the weight of evidence shows that the HMWPEs have a low acute and subchronic toxicity. They are not irritating to the skin or eyes. They are not skin sensitizers. They are not mutagenic. No or only minimal developmental toxicity and no adverse effects on reproductive capability have been observed in rodent studies. Thus, there is minimal concern about these PEs resulting in reproductive toxicity in humans. Although not tested for carcinogenicity, the members of this category do not show the potential for producing genetic effects. Also, the same mechanism of action through peroxisome proliferation can be anticipated for induction of liver tumors in rodents, and this is presumed not to be relevant to humans [374].

6.3. Risk Assessment

Extensive toxicological data on the effects of phthalic acid intermediates and on most of the phthalate esters have been collected and are available to the public [374, 375]. Final EU Risk Assessment Reports are also available for dibutyl-, diisononyl-, and diisodecyl phthalate [375]. In contrast, only draft versions exist for butyl benzyl phthalate and DEHP [375] which are still under discussion because of uncertainties for some key elements, which included the human exposure situation, carcinogenicity, toxicity to reproduction, and implications of species differences.

Carcinogenicity. IARC evaluated the short- and long-term studies regarding genotoxicity and carcinogenicity [376]. It was concluded that there is sufficient evidence in experimental animals for the carcinogenicity of DEHP, but that there is inadequate evidence in humans for the carcinogenicity of DEHP. DEHP was therefore not classifiable as to its carcinogenicity to humans (Group 3).

In making its overall evaluation of the carcinogenicity to humans of DEHP, it was taken into consideration that:

- DEHP produces liver tumors in rats and mice by a non-DNA-reactive mechanism involving peroxisome proliferation.
- Peroxisome proliferation and hepatocellular proliferation have been demonstrated under the conditions of the carcinogenicity studies of DEHP in rats and mice.
- Peroxisome proliferation has not been documented in human hepatocyte cultures exposed

to DEHP or in the liver of exposed nonhuman primates.

Therefore, the mechanism by which DEHP increases the incidence of hepatocellular tumors in rats and mice is not relevant to humans [376]. Similar results were obtained for the other phthalate esters. Consequently, none of these is classified as being carcinogenic to humans.

The overall evaluation is widely accepted [274, 343]. It was, however, pointed out that there are some effects of DEHP that are not receptor-mediated, that peroxisome proliferation is not established as an obligatory step in the carcinogenesis of DEHP, and that therefore the species differences are not viewed as a valid hypothesis for the noncarcinogenicity to humans. It was argued that, independent from peroxisome proliferation and PPARα, DEHP can affect multiple signaling pathways by transcriptional activation of PPARα-regulated genes (suppression of apoptosis, protooncogene experession) and can induce biological effects (morphological cell transformation, decreased levels of gap junction intercellular communication). All these effects could contribute to carcinogenicity, and the precise mechanism of carcinogenic action remains to be determined [246, 274].

Toxicity to Reproduction. Several of the phthalate esters are classified as reproduction toxicants according to European legislation (di-*n*-butyl, di-*n*-pentyl, *n*-pentyl isopentyl, diisopentyl, butyl benzyl, di-2-ethylhexyl, and di-2-methoxyethyl phthalate); however, none is listed as being mutagenic or carcinogenic [377, 401].

6.3.1. Biomonitoring and Human Exposure to Phthalate Esters

Urinary excretion of phthalate ester metabolites (such as monoesters in conjugated or unconjugated form) may be taken as an indirect measure for intestinal absorption. After in vitro hydrolysis of all metabolites phthalic acid may be taken as sum parameter. Urinary MEHP was extensively used in animal and human studies for DEHP exposure estimates. However, there were uncertainties, as during the complex DEHP metabolism MEHP is further metabolized. This suggests that MEHP in blood or urine underestimates the exposure to DEHP, and also that the sum of MEHP and secondary urinary metabolites, namely, 5-OH- and 5-oxo-MEHP, provides a better exposure estimate [188, 203, 378 – 380]. This is widely acknowledged, but debate is ongoing as uncertainties remain regarding the value of earlier studies where the oxidized MEHP metabolites were not measured. This issue was treated among others by the NTP-CERHR Expert Panel during the evaluation of DEHP-related risks to human reproduction in October 2005 [344]. Since the first NTP-CERHR report on DEHP identified data gaps [342] substantial progress was made regarding biomonitoring of phthalate esters in the general population [382].

In 85 urban Germans aged 7–34 years urinary MEHP predicted a median DEHP intake of 13.8 μg kg^{-1} d^{-1} (95th percentile: 38.3); inclusion of the secondary MEHP metabolites gave a median DEHP intake of 10.3 μg kg^{-1} d^{-1} (95th percentile: 52.1) [379, 380].

Urinary MEHP and, for the first time, also 5-OH- and 5-oxo-MEHP, were measured in an U.S. National Health and Nutritional Examination Survey (NHANES) for the period 2001/2002 that included 2782 individuals. It was noted that MEHP levels were comparable to previous reports for U.S. residents [383]. The levels of the secondary metabolites were roughly 5–10-fold higher than MEHP [384]. Thus, they were similar to or up to twofold higher than in German adults and children [379].

Exposure estimates are always higher in children than in adults and highest in medically treated infants, due to the high dose and their low body weights. More recent estimates indicate that in adults and children the exposure to different phthalates is comparable, with the exception of the use of medical devices in children reaching enormous doses. Though doses are higher in children than in adults, the more recent estimates are far lower than those used previously by the NTP-CERHR Expert Panel in exception of the use of DEHP in medical devices 2000. Based on the recent estimates and refined NOAELs the margins of safety (MOS) for all scenarios in Table 9 were reported to be $> 10\,000$, with the exception of use DEHP in medical devices (MOS ≈ 5) [382].

High exposure may result from DEHP leaking out of medical devices during medical treat-

Table 9. Phthalate ester exposure estimates [342, 382]

Phthalate	Exposed group	Exposure estimate [342] in μg kg^{-1} d^{-1}	More recent exposure estimates [382] in μg kg^{-1} d^{-1}
Dibutyl phthalate	adult	2–10	0.86 (3.86) [b]
	young child	not provided	2.65
Butyl benzyl phthalate	adult	2	0.43 (2.08)[b]
	young child	≤ 6	1.64
DEHP	adult	3–30	0.61 (3.51)[b]
	young child (healthy)	10–20	2.57
DEHP, medical-device use	critically ill infant	1800–3300	12 000
Diisononyl phthalate	adult	$<$ 3–30	$<$ LOD (0.73)[ab]
	children using toys	mean $<$ 320	2.91 (10.71)
Diisodecyl phthalate	adult	$<$ 3–30	best analog: diisononyl phthalate
	children	$>$ 3–30	

[a] LOD = Level of detection.
[b] Values are in the format: mean value (95th percentile).

ment of patients and parenteral nutrition of neonates [382, 385, 386]. Estimates are generally far below 1 mg^{-1} kg d^{-1} in adults, but may reach values of 1–8 mg^{-1} kg d^{-1}during extracorporeal membrane oxygenation (ECMO) and large-volume blood transfusions. On the other hand, the plasticizer most commonly employed for medical use, DEHP, and its corresponding monoester MEHP appear to stabilize the membranes of stored erythrocytes [387]. In neonates, dose estimates increase in the order: parenteral nutrition without lipids (0.03 mg kg^{-1} d^{-1}) and with lipids (2.5 mg kg^{-1} d^{-1}) $<$ ECMO (14 mg kg^{-1} d^{-1}) $<$ exchange transfusions (22 mg^{-1} kg d^{-1}) [388]. These exposures are far beyond the TDI value of 50 μg kg^{-1} d^{-1} [389], but only recently, a promising substitute has become available, that lacks toxicity to reproduction and testes [386]: diisononyl cyclohexane-1,2-dicarboxylate (DINCH). DINCH has been successfully introduced into the market and a name plate production capacity of 100 000 tons is currently under construction (BASF AG, personal communication).

In conclusion, the occupational exposure levels resulting from handling and workplace exposure are generally low and well controlled. Exposure estimates for subgroups of the general public covers a wide range for all of the phthalate esters, but more recent data indicate that the exposure levels are much lower than was assumed during the last evaluation of toxicity to reproduction in the year 2000. Only under special circumstances such as parenteral exposure (e.g., eluates from medical devices) may the systemic intake be considerable and of potential toxicological relevance [205, 342, 382, 390, 391]. Dermal resorption has been measured in vitro [341] and in vivo [392] for several phthalate esters and appears to decrease with increasing chain length. The contribution of this route to the total exposure to phthalate esters is considered to be minor compared to the oral and parenteral routes. The significantly enhanced knowledge of exposure situations will improve the assessment of the risks of reproduction toxicity, and it is reasonably expected that the MOS are satisfactory in most scenarios, with the exception of phthalate ester uptake from medical devices. An alternative to DEHP lacking toxicity, DINCH, has only recently been developed and is suited to solve the exposure problems associated with intense medical treatment of patients and neonates.

6.3.2. Carcinogenicity

Hepatomegaly, peroxisome proliferation and related liver effects in rodents are described in Section 6.2.5.4. DEHP exerted a much lower extent of peroxisome proliferation [229] in hamsters. Hepatocytes of guinea pigs, ferrets, marmosets, and humans did not respond with peroxisome proliferation [189, 363]. Marmosets did not show peroxisome proliferation after oral administration of DEHP (2000 mg kg^{-1} d^{-1} for 14 d), whereas in a parallel rat experiment marked peroxisome proliferation was observed [201]. Peroxisome proliferation was also not observed in cynomolgus monkeys which were dosed with 500 mg kg^{-1} d^{-1} of DEHP for 3 weeks [393].

Several reasons for this species difference are assumed: The primary metabolite, MEHP

(see Section 6.2.5.1), undergoes much less glucuronidation in rats. Therefore, renal excretion is much slower in rats, and tissue levels are higher. This has been demonstrated in experiments with rats and monkeys [201, 393]. Furthermore, it was shown that in rats, due to saturation of a final β-oxidation step in the ω-oxidation process, a secondary metabolic pathway (ω-1 oxidation) is induced to a far greater extent, leading to the 5-keto derivate of MEHP, which was shown to be the ultimate peroxisome proliferator [393]. In addition to these kinetic differences, there may also be intrinsic toxicodynamic differences among the species. The overall evidence indicates that human hepatocytes either do not respond to peroxisome proliferators or do so only to a much lesser extent [291]. The conclusion is that, in the case of phthalates, rodent experiments overestimate the risks of chronic toxicity to humans.

6.3.3. Toxicity to Reproduction

DEHP is the model substance to investigate adverse effects and end points in rodents, in primates, and in vitro. Evidently DEHP is a reproduction developmental and developmental toxicant in rodents, but not in primates, that exerts adverse effects on the male reproductive organs and reduces sperm parameters, reduces fertility (increased postimplantation loss) at elevated dose, exerts developmental toxicity to the progeny as substantiated by decreased viability and adverse effects on reproductive parameters of male progeny (adverse effects on reproductive organs, sperm parameters). The underlying mechanisms need further elucidation; toxicity of metabolites to Sertoli cells and interaction with sex hormone regulation are clearly involved, potentially via zinc depletion or receptor interaction. Species differences exist: primates are much more resistant than rodents.

However, mechanisms, potential threshold levels, and species differences are under intense investigation. An update of the evaluation by the CERHR Expert Panel in 2000 [342] was discussed in October 2005 and the final version of the update Expert Panel Report is available since November 2005 [344]. The database is much weaker for other phthalates, but for managing risks the precautionary principle was applied, i.e. many of the short-, intermediate-, and long-chain phthalate esters are considered to act through similar mechanisms as does DEHP, and lead to the same adverse effects.

6.4. Risk Management

Phthalates have been under regulatory scrutiny for more than 20 years because of questions about carcinogenicity and reproductive toxicity, and this has led to some regulatory measures for worker and consumer protection.

In Germany permissible exposure levels (PEL) existed for phthalic anhydride (1 mg/m^3) and 11 phthalate esters. The values stemmed from several European countries and ranged from 3 mg/m^3 (e.g., diethyl, butyl benzyl, dibenzyl, diisodecyl phthalate) and 5 mg/m^3 (e.g., diallyl, dicyclohexyl, diheptyl, dioctyl, dinonyl phthalate) to 10 mg/m^3 for DEHP [394]. However, the scientific basis of the PEL values was regarded to be insufficient, and consequently the PEL values were abolished with the exception of DEHP, which is currently the only phthalate for which a scientifically derived AGW[a] value of 10 mg/m^3 (short-term value: 8-fold) exists. Work is ongoing to establish AGW values for a number of phthalates for which the scientific basis is regarded to be sufficient. These are dicyclohexyl, diheptyl, dioctyl (excluding di-*n*-octyl and DEHP), and dinonyl phthalate, as well as isophthalic and terephthalic acids [395]. The MAK list gives additionally MAK values for isophthalic and terephthalic acids besides DEHP, but these values are not binding. The data basis for phthalic acid, phthalic anhydride, and diallyl phthalate was regarded as being insufficient for deriving an MAK value [396]. Inhalation of vapors, mists, and aerosols is regulated in the USA by TLVs (TWA 5 mg/m^3, STEL 10 mg/m^3 for DEHP, dibutyl phthalate, and dimethyl phthalate).

Regulatory scrutiny led to the voluntary removal of DEHP from children's teethers and toys in 1986, and subsequent pressure to remove others. Since December 1999, the EU has prohibited toys containing more than 0.1 % of six phthalates (di-*n*-butyl, butyl benzyl, di-2-ethylhexyl, dioctyl, diisononyl, and diisodecyl phthalate) that are intendend to be placed in the mouth of children under three years of age

[397]. This temporary ban was strengthened in July 2005 in that di-*n*-butyl, butyl benzyl, and di-2-ethylhexyl phthalate are prohibited in all toys and childcare articles; for the sake of the precautionary principle the regulation remained unchanged for dioctyl, diisononyl, and diisodecyl phthalate [398]. The more recent Directive 2005/84/EC prohibits the use of plasticized materials containing more than 0.1 % of DEHP, DBP, or BBP in toys and childcare articles; or more than 0.1 % of DINP, DIDP, or DNOP in toys or childcare articles which can be placed in the mouth by children. This new regulation was adopted by the EC Member States during 2006, and is effective since January 2007 [399].

There is a general call for substitution of hazardous materials by less hazardous or nonhazardous alternatives. Several applications have been identified or are under investigation in which DEHP could be substituted by less toxic plasticizers, e.g., diisononyl, diisodecyl, or di-2-propylheptyl phthalate, adipates, citrates, alkylated sulfonic esters, trimellitates (in which a third ester group is attached to the benzene ring of phthalates), terephthalates, and cyclohexane-1,2-dicarboxylic esters (DINCH) [400], but there may be limitations that are of technical (e.g., stability), economical (e.g., increased costs), or toxicological and ecological nature (e.g., unknown effect profiles of new substances). Nonetheless, research efforts already led to very promising new solutions and products, notably the substitution of DEHP by DINCH in medical-care products [386].

The former MAK and TRK-values are all abolished and will be stepwise replaced by science-focused AENs (= Arbeitsplatzgrenzwerte)

1. Introduction

The term phthalocyanine was first used by R. P. LINSTEAD in 1933 [4] to describe a class of organic dyes, whose colors range from reddish blue to yellowish green. The name phthalocyanine originates from the Greek terms *naphtha* for mineral oil and *cyanine* for dark blue. In 1930–1940, LINSTEAD et al. elucidated the structure of phthalocyanine (H_2Pc) and its metal complexes [4–14]. The basic structure is represented by phthalocyanine (**1**) itself:

1

Phthalocyanine forms complexes with numerous metals of the periodic table [15–21]. Metal phthalocyanines MPc (**2**) and compounds with metalloids such as B, Si, Ge, and As or nonmetals such as P display a wide variety in their coordination chemistry.

2

The coordination number of the square planar complexes of Cu, Ni, or Pt is 4. Higher coordination numbers of 5 or 6 with one or two additional ligands such as water or ammonia result in square-based pyramidal, tetrahedral, or octahedral structures (**3**) [22–25]. Complexes

9

of lanthanides and actinides (e.g., $Nd^{III}HPc_2$ or $U^{IV}Pc_2$) have an unusual sandwich structure (**4**) with eight coordinated N atoms [26–28]. In contrast, reaction of 1,2-dicyanobenzene with uranium chloride in DMF gives a phthalocyanine ring with five isoindole units (**5**; super phthalocyanine) [29], [30]. A boron compound (**6**) with three former dinitrile units can be synthesized from boron halides and 1,2-dicyanobenzene [31].

3

4

5

6

Phthalocyanines form polymers in which the central atom is a part of the polymeric chain. Elements such as Si^{IV}, Ge^{IV}, or Sn^{IV} yield covalently bonded polymers (**7**) [32–37]. The degree of polymerization n ranges from 65 to 140 for $(SiO_2Pc)_n$.

7

The phthalocyanines are structurally related to the macrocyclic ring system porphyrin (**8**). Formally, phthalocyanine can be regarded as tetrabenzotetraazaporphyrin and as the condensation product of four isoindole units (see above).

The phthalocyanines are structurally similar to naturally occurring porphyrins such as hemoglobin (**9**), chlorophyll a, vitamin B_{12} and turacin (a red dye from the wings of an African bird) [39]. Phthalocyanines themselves do not occur in nature.

Compounds with naphthalene or anthracene rings in place of the benzene nucleus also belong to the phthalocyanine family. The hydrogen atoms of benzene rings can be substituted in many ways (e.g., by halogens or by sulfonic acid, sulfonyl chlorides, or chloromethyl groups) (Chap. 5). Various polymers with interesting properties can be synthesized.

History. Braun and Tschernak [40] obtained phthalocyanine for the first time in 1907 as a byproduct of the preparation of *o*-cyanobenzamide from phthalimide and acetic anhydride. However, this discovery was of no special interest at the time. In 1927, de Diesbach and von der Weid prepared CuPc in 23 % yield by reacting *o*-dibromobenzene with copper cyanide in pyridine [41]. Instead of the colorless dinitriles, they obtained deep-blue CuPc and observed the exceptional stability of their product to sulfuric acid, alkalies, and heat. The third ob-

servation of a phthalocyanine was made at Scottish Dyes, in 1929 [42]. During the preparation of phthalimide from phthalic anhydride and ammonia in an enamel vessel, a greenish blue impurity appeared. DUNSWORTH and DRESCHER carried out a preliminary examination of the compound, which was analyzed as an iron complex. It was formed in a chipped region of the enamel with iron from the vessel. Further experiments yielded FePc, CuPc, and NiPc. It was soon realized that these products could be used as pigments or textile colorants. LINSTEAD et al. at the University of London discovered the structure of phthalocyanines and developed improved synthetic methods for several metal phthalocyanines from 1929 to 1934 [4–14]. For example, the reaction of dicyano aromatics and metal salts was patented in 1939 [43]. The important CuPc could not be protected by a patent, because it had been described earlier in the literature [41]. Based on LINSTEAD's work the structure of phthalocyanines was confirmed by several physicochemical measurements [44–50]. Methods such as X-ray or electron microscopy verified the planarity of this macrocyclic system. Properties such as polymorphism, absorption spectra, magnectic and catalytic characteristics, oxidation and reduction, photoconductivity and semiconductivity, solubility, and photochemical and dielectric properties were investigated from the 1930s to the 1950s.

Copper phthalocyanine was first manufactured by ICI in 1935, where its production from phthalic anhydride, urea, and metal salts was developed [51]. Use of catalysts such as ammonium molybdate improved the method substantially [52]. In 1936, I.G. Farbenindustrie began production of CuPc at Ludwigshafen, and in 1937 Du Pont followed in the United States. The most important of the phthalocyanines, CuPc, is now produced worldwide. The first phthalocyanine dye was a phthalocyanine polysulfonate [42]. Other derivatives, such as sulfonyl chlorides, ammonium salts of pyridyl phthalocyanine derivatives, sulfur and azo dyes, and chrome and triazine dyes, have been patented since 1930. At that time, the use of phthalocyanines as colorants for printing ink, paint, plastics, and textiles began. Of the industrial uses, the application of CuPc in printing inks is its most important use. The greenish blue CuPc shade is suitable for color printing. Other favorable properties such as light, heat, and solvent resistance led to the use of this blue pigment for paints and plastics. The chloro and bromo derivatives are important green organic pigments. Other derivatives are used in textile dyeing and printing or for the manufacture of high-quality inks (pastes for ballpoint pens, ink jets, etc.).

2. Physical Properties

2.1. General Data

The molecular mass of phthalocyanine, $C_{32}H_{18}N_8$, is 514.55. The densities of Pc compounds depend strongly on chemical composition:

β-H_2Pc	ϱ=1.43 g/cm^3
β-CuPc	1.61 g/cm^3
Polychloro CuPc	2.14 g/cm^3
β-CoPc	1.50 g/cm^3
β-NiPc	1.59 g/cm^3

The color of most Pc's ranges from blueblack to metallic bronze, depending on the manufacturing process. Ground powders exhibit colors from green to blue. Most compounds do not melt but sublime above 200 °C, which can be used for purification. An exception is $Si(OC_{18}H_{37})_2Pc$, which melts at 152 °C [53].

Solubility and Thermal Stability. H_2Pc, CuPc, and halogenated phthalocyanines have very poor solubility in organic solvents. Only in some high-boiling solvents such as quinoline, trichlorobenzene, and benzophenone is recrystallization possible at higher temperature. However, the solubilities have a maximum of several milligrams per liter. In common solvents such as alcohols, ethers, or ketones the solubility is considerable lower. One liter of benzene dissolves 0.15 mg of α- or γ-CuPc and 0.046 mg of β-CuPc at 40 °C [54]. The heats of solution are 34.3 kJ/mol for α-CuPc and 41.4 kJ/mol for β-CuPc [54]. The solubilities of other Pc complexes depend on the central atom.

Phthalocyanine and its unsubstituted metal derivatives dissolve in highly acidic media such as concentrated sulfuric acid, chlorosulfuric acid, or anhydrous hydrofluoric acid, presumably due to protonation of the bridging nitrogen atoms [55–57]. In the presence of strong bases, reversible deprotonation of the central imino

groups occurs [57]. The solubility in sulfuric acid depends on temperature and concentration [58]. In particular, the removal of copper from solid phthalocyanine by 25 – 65 % H_2SO_4 at 25 – 70 °C ranges from 0.6 to 9.2×10^{-6} mol/L after 5 to 100 h. The rate of decomposition of CuPc increases with increasing H_2SO_4 concentration, reaching a maximum at about 80 % H_2SO_4. The stability of metal phthalocyanines increases in the order: ZnPc<CuPc<CoPc <NiPc<$CuPcCl_{15}$ [59]. The color of phthalocyanine solutions in sulfuric acid depends on the degree of protonation (the N atoms of the ring systems are protonated by H_2SO_4; metals, e.g., Cu influence this protonation): H_2Pc gives a brownish yellow color; CuPc, greenish yellow to olive. The phthalocyanines can be precipitated from these solutions by addition of water. CuPc dissolves to the extent of 20 mg in 100 mL of liquid ammonia at − 33.5 °C [60]. Solubility can be improved in some cases by reversible oxidation with organic peroxides or hypochlorites; the Pc's are oxidized to substances soluble in organic solvents from which they can be regenerated by reduction [61].

Both H_2Pc and its derivatives exhibit high thermal stability. For example, CuPc can be sublimed without decomposition at 500 – 580 °C under inert gas and normal pressure [8]. In vacuum, stability up to 900 °C has been reported [62]. Polychloro CuPc is thermally stable up to 600 °C in vacuum. At higher temperature it decomposes without sublimation. CuPc decomposes vigorously at 405 – 420 °C in air. In nitrogen, sublimation and decomposition occur simultaneously at 460 – 630 °C [63], [64]. Generally all metal Pc's are more stable thermally in N_2 than in O_2. CuPc changes from the α- to the β-form at 250 – 430 °C [65]. Several MPc polyimides exhibit good thermal and thermooxidative stability at > 500 °C in air and nitrogen, and are therefore of interest for heat-stable films, coatings, and fibers [66].

2.2. Particle Size

Particle size and particle-size distribution are important criteria for Pc's used as pigments; they can be determined by the Debye – Scherrer-method [67], [68]; by adsorption measurements [67], [69], [70]; or by electron microscopy [67], [70–75]. The particle size calculated from adsorption data is ca. 0.044 µm for α-CuPc, 0.054 µm for β-CuPc, and 0.037 µm for polychloro CuPc [73].

The particle size of pigments dispersed, for example, in paint or printing ink binders can be determined by sedimentation analysis in centrifuges [69], [70], [75–79]. The particle diameters measured by this method are larger than those obtained by electron microscopy [69], [70]. This is due to incomplete dispersion of agglomerates from the pigment powder. These agglomerates can be dispersed totally only by prolonged grinding [69]. Lattice dimensions and crystal defects can be determined from the diffraction pattern that appears on high magnification under the electron microscope [80]. The particle size and particle form of Pc pigments are discussed in [70], [71], [73], [81].

2.3. Color Properties

Phthalocyanines absorb strongly in the visible range of 600 to 700 nm. They are thus blue to blue-green colorants. Their absorption spectra in solution are very different from those of the solids. The color of solid pigments is also influenced by the crystal modification [54], [82]. Color properties may depend to some extent on pleochroistic effects [70], [79] and on the nature of the central metal atom. In the series metal-free H_2Pc, NiPc, CuPc, CoPc with the same crystal modification, the color shifts from strongly greenish blue to strongly reddish blue, and the color purity decreases. The only metal phthalocyanine with a brilliant color suited for the cyan tone in color printing is CuPc. Color strength increases with decreasing particle size of the crystals, aggregates, and agglomerates. Figure 1 illustrates this for β-CuPc and polychloro CuPc [75].

Substitution of the benzene rings in phthalocyanine results in a color shift to greenish blue or green. Polychloro CuPc is bluish green. Partial substitution of the Cl atoms by Br atoms results in a yellowish green. Alkyl, aryl or other functional groups have a similar effect (Chap. 5.). A red shift can be attained by replacement of benzene rings by pyridine rings [83]. This compound has a more turbid color shade than CuPc, but it exhibits similar pigment properties.

2.4. Crystal Structure and Polymorphism

The crystal structure and polymorphism of phthalocyanines are reviewed in [84–87]. These are among the first organic solids whose crystal structures were determined by X-ray analysis of single crystals [45], [47], [48]. Phthalocyanine and its important metal derivatives (Fe, Co, Ni, Cu, Pt) have monoclinic lattices. Lattice constants and other X-ray data are tabulated in [88], [89]. The Pc ring system is always planar. Bond lengths and angles are influenced only slightly by the nature of the central metal atom [89]. Phthalocyanine and its metal derivatives occur in different crystal modifications [90], which has been shown by X-ray analysis and by IR and ESR spectroscopy. The modifications of H_2Pc, CuPc, and other derivatives differ in regard to color and physical properties. Five polymorphous modifications of CuPc are known; they are designated α, β, γ, δ, and ε [54]. Two more modifications have been described in the literature [27], [91–96].

According to their solubilities in benzene (good solubility implies instability), thermodynamic stability increases in the sequence $\alpha=\gamma<\delta<\varepsilon<\beta$ [54]. The enthalpy difference between α- and β-CuPC is 10.75 kJ/mol [97]. Three modifications of $H_2Pc-\alpha$, β [98], [99], and X [100] – have been found. Polychloro CuPc has only an α-modification [93], which is related to the α-modification of CuPc. All modifications exhibit one-dimensional stacking of the molecules (Fig. 2). However, the arrangement of the stacks with respect to one another differs, as illustrated by the structures of α- and β-CuPc (Fig. 2).

Figure 2. Arrangement of copper phthalocyanine molecules in the α- and β-modifications
The planar molecules appear as lines in this projection.

Phase transformations in crystals are of interest, impelled by the fact that the most desirable pigment in terms of color properties in a given medium may not be the most resistant to changes in crystal modification [2], [3], [54], [101]. During synthesis the most stable modification is formed; in the case of CuPc and H_2Pc this is the β-modification. Dissolving β-CuPc in concentrated sulfuric acid or treatment with 40 – 90 % sulfuric acid yields the finely divided α-form, after hydrolysis of the greenish yellow sulfate [2], [3], [99]. The β-modification is often converted to the α-modification by dry grinding in the presence of additives (e.g., salts). Figure 3 shows examples of the temperature-dependent $\beta \rightarrow \alpha$ transition by dry grinding. The rate of transformation decreases with increasing temperature.

Figure 3. The $\beta \rightarrow \alpha$ transformation by dry grinding as a function of grinding time and temperature
a) 70 °C; b) 90 °C; c) 110 °C; d) 130 °C

Preparation of the γ- [102], δ- [103], and ε-modifications [104], [105] is described in the literature, and further modifications (π, x) are believed to exist [27], [91–96], [106]. All modifications can be transformed into the most stable form by heating in a high-boiling, inert solvent. In the absence of solvent, the transformation occurs at ca. 200 °C [2], [3]. Crystal growth has been studied by X-ray diffraction and electron microscopy [107], [108]. The transformation of CuPc in various organic media has been studied by electron microscopy and X-ray diffraction [109]. The preliminary growth of metastable α crystals precedes the transition to stable β crystals. Other studies of the $\alpha \rightarrow \beta$transition by visible spectroscopy, X-ray diffraction, electron microscopy, and BET determination of the specific surface area [110] indicate a three-stage process in terms of the classical theories of nucleation and crystal growth:

1) Ostwald ripening of the α-phase and nucleation of the β-phase
2) Disappearance of the α-phase and production of the β-phase
3) Final crystallization and ripening of the β-phase

The process is determined by nucleation of the stable phase [54], [111]. Treatment of β-CuPc with boiling solvents causes the β crystals to grow; treatment of α-CuPc with solvents causes the crystals to grow before transition to theβ-phase occurs, and the β crystals grow [112]. The behavior of metal phthalocyanines depends on the central metal ion [113]. Suspending α-CuPc with metal oxides such as alumina, magnesia, or zinc oxide in organic media results in an acceleration of the $\alpha \rightarrow \beta$ transformation [114]. Solvent-stable, flocculation-resistant α-, β-, and γ-modifications of CuPc and NiPc are prepared by combining phenyl-, chloro-, and sulfo-substituted tetraazaporphyrins with the MPc [115].

2.5. Surface and Interfacial Properties

A variety of surface and interfacial properties have been studied [2][3]. They include the effects of size reduction or milling, surface ionization energies [116], orientation overgrowth (epitaxial growth of crystals on a substrate surface) [117], the change of surface properties on crystal transformation [118], electric and photoelectric effects, interphase surface activity [119], and measurement of surface free energy and polarity [120]. Interfacial properties such as heats of adsorption and adsorption isotherms with organic liquids and water demonstrate the hydrophobic character of phthalocyanine pigments, which is in contrast to many organic and inorganic pigments [70], [73], [121]. In their properties, Pc's are very similar to graphite or diamond powder. Flocculation stability and rheological properties are influenced disavantageously. This effect, however, can be counteracted by addition of hydrophilic phthalocyanine derivatives [122–124]. In dispersions in organic media such as paints and binders, CuPc and polychloro CuPc are electrostatically charged [125], [126]. However, in contrast to many aqueous systems, this does not lead to stabilization of the dispersions. Adsorption of polymers improves flocculation stability. Both positive and negative charges are present on the same CuPc particles, which promotes flocculation, especially for rodlike structures [126]. Theoretical and experimental studies of the adsorption of a variety of organic compounds on phthalocyanines support the theory of privileged sites for adsorption on phthalocyanine at the central metal atom and along certain axes [127]. The stacking of phthalocyanine molecules results in two different surfaces. The surface parallel to the longitudinal axis of the stack is characterized primarily by benzene ring substituents (nonpolar hydrogen atoms). At the base of the stack, the dominant structural units are π-systems (nitrogen atoms and the central metal atom). Only the bases of the acicular crystals consist of easily polarizable atoms [128].

The specific surface area *s* of CuPc decreases on heating in vacuum at 300 °C from ca. 90 to 45 m^2/g, and its coloring power decreases by 10 % [2], [3], [121]. In vacuumα-CuPc , has *s*=30, 11, and 4 m^2/g at 20, 200, and 300 °C, respectively [121].

2.6. Other Physical Investigations

The physical properties of phthalocyanines have been investigated theoretically and in regard to application as semiconductors, catalysts, etc., by

a variety of physical methods. Absorption, fluorescence and phosphorescence, NMR, IR, Raman, and ESR spectra, as well as electric, photoelectric, magnetic, and semiconductor properties, are reviewed in [2], [3], [15], [129–133]. Some of these properties depend on the purity of the compounds [134]. The relationship to the catalytic properties of some Pc's is given in [135]. Mössbauer, ESCA, and inelastic tunneling spectroscopy, along with field ion and field electron microscopy, are reviewed in [2][3], [136], [137–140]. Although many of these physical properties suggest possible applications of phthalocyanines in semiconductors, catalysts, lubricants, lasers, or photography, they have not yet been exploited industrially.

3. Chemical Properties

The chemical properties of phthalocyanines are determined by the nature of the central atom, with each complex undergoing specific reactions. Nevertheless, some properties are universal.

3.1. Oxidation

The behavior of phthalocyanines upon electrochemical or chemical oxidation and reduction is important for determination of the redox potentials [141], [142] by cyclic voltametry or polarography, for the use of Pc's in preparative chemistry, and for application in photoredox processes [20]. Compared to porphyrins, phthalocyanines are easy to oxidize or reduce [20]. Oxidation can be reversible or irreversible, depending on the conditions. Phthalocyanines are stable to atmospheric oxygen up to ca. 100 °C. Stability depends on the central metal atom [143]. In aqueous solutions of strong oxidants, the phthalocyanine ring system is completely destroyed. Oxidation of one molecule of CuPc consumes one oxygen atom, which was confirmed by oxidation with cerium(IV) sulfate in sulfuric acid [10]:

$$[C_8H_4N_2]_4Cu + 3H_2SO_4 + 7H_2O + [O] \longrightarrow 4\,C_8H_5O_2N + CuSO_4 + 2(NH_4)_2SO_4$$

The phthalocyanine ring is oxidized to phthalimide. This reaction can be used for quantitative determination of CuPc content. Other possibilities are oxidation with sodium vanadate [144], nitric acid [145], or potassium dichromate in sulfuric acid [146]. During oxidation of CuPc, intermediates with an intense violet color are formed [8], [147–150]. Addition of a solution of CuPc in concentrated sulfuric acid to ice water containing 3 % nitric acid gives a violet precipitate, which can be converted back to the pigment by drying [151]. The stability of CuPc toward ozone indicates that this oxidant has little or no effect on its structure [152]. Adducts of $Fe^{II}Pc$, $Cr^{IV}Pc$, $Mn^{II}Pc$, and $Co^{II}Pc$ with nitrogen oxides are also known [151]. Well-defined oxidation products of phthalocyanines can be obtained in nonaqueous solution. Either oxidation occurs in the ring system, or the oxidation state of the central metal atom is changed. Oxidation of the ring system yield derivatives of tetracycloindolenines **10** and **11** [153], [154].

10 **11**

Oxidation with nitric acid in toluene, acetic acid, methanol, or pyridine yields **10** and **11**, with R=OH. Bromine in methanol or methanol – pyridine gives alkoxy or bromine derivatives (R=OCH_3 or Br) [61], [153], [154]. Acyl peroxides lead to acyl derivatives (R=OCOR) [154].

Oxidation products **10** and **11** are formed by metal-free phthalocyanine and MPc (M=Mg, Zn, Fe, Co, Ni, and Cu) [154]; polychloro CuPc does not react in this way. These oxidation products are much lighter than the blue dyes. For example, the nitrate of CuPc is yellow, and that of CoPc, yellow-orange [61], [153], [154]. Many of these complexes are crystalline and stable in the absence of reducing agents. They can be reduced to the corresponding Pc's in good yield [153], [154]. The same effect is observed on heating to 140 – 220 °C [61]. The good solubility of the oxidation products in organic solvents

such as chloroform, pyridine, DMF, and methanol is noteworthy. These phthalocyanine derivatives are of considerable industrial interest for textile dyeing. Their synthesis and applications are described in many patents (see Chap. 8).

Oxidation can also occur at the central metal atom of the phthalocyanine system. Transition metals, which occur in several oxidation states, exhibit this behavior. They usually form six-coordinate complexes on oxidation:

The chemistry of these metal phthalocyanines is reviewed in [15]. Manganese phthalocyanine, which occurs in five oxidation states from 0 to +4, is unique in this context [15]. Synthesis from manganese and phthalodinitrile yields $Mn^{II}Pc$ (**12**) [11]. Oxidation in organic solvents such as alcohol or chloroform or in the presence of a trace of acid yields $Mn^{III}Pc$ (**13**). In pyridine, dimethyl sulfoxide, diethylamine, or alkaline alcohol, this is converted to $Mn^{IV}Pc$ (**14**) [155–157]. The $Mn^{II}Pc$ reversibly chemisorbs oxygen in pyridine, which was first demonstrated by ELVIDGE and LEVER [156]. The oxygen absorbed at room temperature in pyridine solution can be removed by heating to boiling temperature. This process can be repeated several times, whereby small amounts of the phthalocyanine complex are decomposed. The mechanism of the process follows [157], [158]:

Complex **13** is not very stable; irradiation with light causes reduction to **12**. In the dark, **13** disproportionates to **12** and **14**. In the presence of oxygen, the oxidation of **13** continues to give **14**. In **14**, the manganese atoms are bridged by oxygen atoms [159]. This reversible uptake of oxygen seems to be analogous to oxygen transfer by heme, in which oxygen is fixed by a π-bond in the first step [160]. The catalytic properties of other phthalocyanines (e.g., FePc) can be interpreted in the same way [161].

Reduction of MnPc with lithium benzophenone in the presence of tetrahydrofuran results in formation of the lithium salt of $Mn^{I}Pc$ and the dilithium salt of $Mn^{0}Pc$ [162], [163].

The compound $Co^{I}Pc$ can be converted to $RCo^{III}Pc$ by reaction with alkyl halides [20], [164], [165]; $Co^{I}Pc$ can also be used as a selective reducing agent for aliphatic or aromatic nitro compounds [166] and as a reagent for cleaving β-halo alkyl groups, which are widely used to protect amino, carboxyl or phosphoryl groups in nucleotide or peptide chemistry [167]. Applications of MPc in ammonia synthesis [20], [168–170], Fischer–Tropsch synthesis [171], [172], or hydroformylation [173] are described in the literature.

3.2. Reduction

Either the central metal atoms or the carbon atoms of the phthalocyanine ring system can be reduced. The totally reduced form of the ring system, hexadecahydrophthalocyanine (**15**), can be produced from 3,4,5,6-tetrahydrophthalodinitrile [174].

15

In reversible reduction, electrons are removed from the inner ring system or the central metal atom. In alkaline sodium dithionite solution, for example, conversion to a leuco form is

possible [42], [55], [175], [176]. The reduction products are weakly colored: greenish for CoPc and brownish yellow for FePc. With reducing agents such as alkali metals, multiple reductions ($MPc + n\,e^- \rightarrow MPc^{n^-}$; n=1 – 5 for Mn, n=1 – 4 for Ni) should be possible [20], [177]. For example, CuPc can be reduced with potassium in liquid ammonia [178], [179]. The solubility of the leuco form is usually too low for industrial purposes (e.g., CoPc). It can be increased by partial sulfonation. Indanthrene brilliant blue 4 G (C.I. Vat Blue 29, 74 140) is used for spin dyeing [180]. Although the structure of the leuco form has not been determined totally, a structure of type **16** can be assumed [181].

16

Reduction products with similar structures are known for other metal phthalocyanines [1, pp. 278 – 279]. Depending on the metal, reduction can take place either only in the ligand (Ni, Cu, Zn, Li) or first in the metal and then in the ligand (Cr, Mn, Fe, Co) [182].

3.3. Catalytic Properties

Many metal phthalocyanines, particularly the transition-metal complexes, can bind further ligands to form octahedral complexes. In some cases, this is accompanied by a change in oxidation state. This phenomenon is related to the catalytic properties exhibited by many members of this class of compounds [2, p. 61], [134], [135].

Two review articles deal with heterogeneous catalysis in dehydrogenation, oxidation, and electrocatalysis [183] and heterogeneous catalysis in gas-phase reactions by metal Pc's [184]. Catalysis by metal phthalocyanines was first discovered in 1936 in the exchange reaction between molecular hydrogen and water and the catalysis of water formation from oxygen and hydrogen [185]. Oxygen transfer reactions and catalysis of the decomposition of hydrogen peroxide were described later [186]. This suggested the similarity of metal phthalocyanines to heme and to enzymes such as hydrogenase [187]. Oxygen transfer reactions, particularly of iron phthalocyanines, were later observed in other reactions. Alkanes, olefins and aromatics, alcohols, aldehydes, alkyl aromatics, phenols, amines, thiols, cumenes, polymers, and sugars are oxidized by molecular oxygen in the presence of iron, copper, or cobalt phthalocyanine. In addition, hydrogenation, dehydrogenation, degradation, polymerization, isomerization, hydrogen-exchange reactions, reductive dehalogenation, hydrogenative thermal cracking, autooxidation, epoxidation, decarboxylation, and Fischer – Tropsch synthesis are catalyzed by phthalocyanines [2, p. 61], [3, I, p. 79 – 102], [15, p. 92], [134], [135], [183], [184].

A major interest in the reduction of molecular oxygen by Pc catalysts is the development of fuel cells [188]. The recognition of phthalocyanines as oxygen reduction catalysts is due to Jasinski, Jahnke, and Schoenborn, who studied catalysts for electrochemical reactions in fuel cells [189–192]. The phthalocyanines were the first platinum-free catalysts suitable for this purpose. The electrocatalytic activity of metal Pc's depends considerably on the central metal ion [161], [186], [193]. The order of decreasing electrocatalytic activity is Fe>Co>Ni>Cu>H, with H_2Pc having very low activity [3, I, p. 81]. The high activity and stability of FePc electrodes are reported in [194], [195]. Light is involved in the electrocatalytic reduction of oxygen by FePc, CuPc, and H_2Pc on a graphite carrier [2, I, p. 81]. Phthalocyanines also catalyze the reduction on carbon cathodes of substances other than oxygen [196].

The mechanism of these heterogeneous catalysts is basically similar to that of other solid catalysts. An advantage is the homogeneity of the active centers. In contrast to the usual catalysts, the metal atoms here are always within the same electronic surrounding of the macromolecule in the surface of the crystals. Depending on the structure of the electron shells of the metal atoms, adducts can be formed with the reactants [161], [197], [198]. The catalytic activity is therefore closely related to the interactions between substrate and catalyst [197]. Activity increases with increasing electrical con-

ductivity of the solid phthalocyanines [135] and is also influenced by the carrier material [199]. The stability of metal complexes in the presence of other chemicals is still a problem, and in fact the most active compounds are often the least stable [161]. Polymeric phthalocyanines exhibit higher stability [134].

Polymeric CoPc, for example, is an effective catalyst in secondary fuel cells. The oxygen formed in electrolysis is stored in the polymer matrix and reduced during electrochemical discharge [200]. Sulfonic acids of CoPc and CuPc are used in the oxidation of thiols in crude oil [2, p. 300], [201].

4. Production

4.1. General Synthetic Methods

Phthalocyanine complexes have been synthesized with nearly all the metals of the periodic table [1], [15], [21]. Despite the apparently complex structure of the Pc system, it is formed in a single-step reaction from readily available starting materials. The reaction is strongly exothermic. For example, the synthesis of CuPc from phthalodinitrile ($4\,C_8H_4N_2 + Cu \rightarrow C_{32}H_{16}N_8Cu$) has a reaction enthalpy of -829.9 kJ/mol. The low energy of the final product can be accounted for by resonance stabilization; this explains at least partially the relatively facile formation of the complex. The most important metal phthalocyanines are derived from phthalodinitrile, phthalic anhydride, Pc derivatives, or alkali-metal Pc salts.

From *o*-Phthalonitrile.

where M is a metal, a metal halide (MX_2), or a metal alkoxide [$M(OR)_2$]. The reaction is carried out in a solvent at ca. 180 °C or by heating a mixture of solid reactants to ca. 300 °C.

From Phthalic Anhydride.

$$\longrightarrow MPc + 4\,CO_2 + 8\,H_2O + X_2$$

This synthesis is carried out either in a solvent at 200 °C or without solvent at 300 °C.

From phthalimide derivatives, e.g., diimidophthalimide.

*from reducing agent

This synthesis is carried out in a solvent (e.g., formamide).

From Alkali-Metal Pc Salts. Dilithium phthalocyanine can be used as starting material for the production of other metal Pc's. The reaction is carried out in a solvent.

$$Li_2Pc + MX_2 \longrightarrow 2LiX + MPc$$

Metal-free phthalocyanine is obtained by the following procedures [1], [2], [3], [15]:

1) Decomposition of an unstable MPc with alcohol or acid

$$PcNa_2 + 2H_3O^+ \longrightarrow PcH_2 + 2Na^+ + 2H_2O$$

2) Direct synthesis (e.g., from phthalodinitrile)

Syntheses of MPc from phthalodinitrile or phthalic anhydride in the presence of urea are the two most important laboratory and industrial methods. They were also used originally by LINSTEAD and coworkers [11], [12]. This procedure allows the production of many phthalocyanine compounds [1], [2], [3]. Catalysts such as boric acid, molybdenum oxide, zirconium and titanium tetrachloride, or ammonium molybdate are used to accelerate the reaction and improve the yield [2][3]. Ammonium molybdate is especially effective. Reaction is carried out either in a solvent or by heating the solid components. When metal chlorides and phthalodinitrile are used as starting materials, the reaction products are partially chlorinated:

Lowering the reaction temperature or adding urea or basic solvents decreases the extent of chlorination. Solvents such as nitrobenzene, trichlorobenzene, alcohols, glycols, pyridine, and aliphatic hydrocarbons are employed. By using substituted phthalic acid compounds such as 4-chlorophthalic acid anhydride, 4-sulfophthalic acid anhydride or 4-nitrophthalimide, phthalocyanines with inner substitution can be produced. The products can often be purified by sublimation in vacuo at 300–400 °C. Soluble Pc's can be purified by recrystallization.

4.2. Reaction Mechanism

In the synthesis of phthalocyanines from phthalodinitrile or from pthalic anhydride and urea, intermediate isoindolenines (**17**) and polyisoindolenines are formed. According to [153], isoindolenines (**17**) are formed in the first step from dinitrile and polar compounds as follows:

17

Metal salts, ammonia, primary or secondary amines, hydrogen sulfide, hydrogen bromide, or alkoxides are used as polar compounds. The isoindolenines condense to form the ring system around a central metal atom.

The intermediates cannot be isolated under normal synthesis conditions of ca. 200 °C. Some phthalocyanine developing dyes however use these intermediates, which react with metal salts on the fiber to give metal phthalocyanines (Chap. 8) [2], [3], [153], [202].

The synthesis of phthalocyanine from phthalic anhydride or similar phthalic acid derivatives also results in the formation of an intermediate compound [1], [2], [3]:

The 1,3-diiminoisoindolenine can be isolated as the nitrate [153].

In a urea melt, the reaction involves formation of polyisoindolenines and their reaction with copper salts to form CuPc. Synthesis with ^{14}C-labeled urea or phthalimide showed that the urea carbon atom is not incorporated into the phthalocyanine framework but is released as ^{14}CO [203], [204].

4.3. Industrial Production

4.3.1. Copper Phthalocyanine

Two processes are commonly used for the production of copper phthalocyanine: the phthalic anhydride–urea process patented by ICI [51], [52] and the I.G. Farben dinitrile process [205]. Both can be carried out continuously or batchwise in a solvent or by melting the starting materials together (bake process). The type and

amount of catalyst used are crucial for the yield. Especially effective as catalysts are molybdenum(IV) oxide and ammonium molybdate. Copper salts or copper powder is used as the copper source [1], [2], [3]; use of copper(I) chloride results in a very smooth synthesis. Use of copper(I) chloride as starting material leads to the formation of small amounts of chloro CuPc. In the absence of base, especially in the bake process, up to 0.5 mol of chlorine can be introduced per mole of CuPc with CuCl, and up to 1 mol with $CuCl_2$. During pigment finishing (Section 4.4) these products can be processed to the stable α-modification, but not to the β-modification, of copper phthalocyanine.

The patent literature gives details of modifications and refinements of the original processes. A review of older processes is given in [1], [2], whereas examples of more modern production methods are described in [3], [206].

As apparatus for the batch process, an enamel or steel reactor with an agitator and pressure steam or oil heating suffices. Apparatuses used in the continuous synthesis in the presence of solvents and in the bake process are described in [207] and [208], [209], respectively. The choice of process depends on the availability and cost of the starting materials phthalodinitrile or phthalic anhydride. Although the phthalodinitrile process has certain advantages over the phthalic anhydride process, the latter is preferred worldwide because of the ready accessibility of phthalic anhydride. In this process the molar ratio of phthalic anhydride, urea, and copper(I) chloride is 4:16:1, with ammonium molybdate as catalyst. The mixture is heated in a high-boiling solvent such as trichlorobenzene, nitrobenzene, or kerosene. The solvent is removed after the formation of copper phthalocyanine. Frequently a purification step follows. A few typical examples are described below.

Phthalic Anhydride – Urea Process [52], [141, pp. 274 – 278]. Phthalic anhydride (100 kg), urea (135 kg), and trichlorobenzene (300 kg) (technical isomer mixture) are mixed in a 1000-L vessel, equipped with an oil bath and stirrer; 24 kg of copper(II) chloride and 0.5 kg of ammonium molybdate are then added. The mixture is heated up slowly within 1 h to 200 °C. Gas evolution (mostly CO_2 and some NH_3) with formation of phthalimide begins at 130 °C. Formation of CuPc begins at 160 – 170 °C, with simultaneous release of CO and NH_3. After stirring at 200 – 205 °C for 1 h, formation of the pigment is complete. The phthalocyanine is filtered off; washed with hot trichlorobenzene, trichlorobenzene at 50 °C, methanol, and hot water; and dried. The yield of CuPc is 87 kg (90 %).

Carrying out the reaction under pressure gives a high-purity CuPc pigment [210].

Several *dry processes* have also been described [3, II, p. 32].

In one of these [211], urea, copper(II) chloride, and ammonium molybdate are ground for 4 h in a ball mill, phthalic anhydride is added, and grinding is continued for 80 min. A small amount (10 to 60 % of the weight of phthalic anhydride) of solvent (nitrobenzene, naphthalene, or dodecylbenzene) is added, and the slurry is spread in stainless steel pans. These are heated in an oven at 195 °C for 8 h. The product is ground and slurried in dilute hydrochloric acid, filtered hot, washed with water, and dried. The yield is 84.5 – 86.6 % or 88 – 90 % when the reaction is carried out in a paddle drier [3].

The solvent can be replaced by ammonium chloride [212], a fourfold excess of phthalic anhydride, sodium chloride [213], or a 1:1 $NaCl-MgCl_2$ mixture [3], [214]. In the dry reaction, the ammonium molybdate catalyst can be replaced by a molybdenum or molybdenum alloy agitator [2], [3].

Another dry process is run continuously [215]. The dry, powdered reaction mixture is fed into a rotary furnace kept at 180 °C, and the dry product is discharged into a drum at a yield of 96 % [2], [3]. A vacuum method for the preparation of relatively pure CuPc is described in [216].

Phthalodinitrile Process. In the bake process [143, pp. 343 – 344], 100 kg of phthalodinitrile (ca. 95 % pure) is mixed with 24 kg of dry CuCl (1.25 mol) and 400 kg of anhydrous Na_2SO_4. The mixture is then slowly passed through a tunnel dryer within 1 h at 200 °C. The baked mixture is washed with hot water and 1 % hydrochloric acid, filtered off, and dried. The process can be carried out continuously.

One improvement of the process consists of grinding 100 kg of phthalodinitrile, 19 kg of anhydrous CuCl, and 20 kg of urea; mixing the

powder thoroughly (or grinding in a ball mill); and heating it to 150 °C. The temperature increases to 310 °C due to the heat of reaction, thus completing the reaction within a few minutes. After purification the yield is 97 %, and the product contains 0.3 % Cl [3, II, p. 30], [217]. Carrying out the reaction in the presence of a salt that decomposes at 30 – 200 °C to form ammonia improves the yield [218].

The reaction has also been carried out in solvents such as trichlorobenzene in the presence of pyridine [143]. Pyridine converts the insoluble copper(I) chloride into a soluble complex, which reacts more quickly.

A mixture of 300 kg of trichlorobenzene, 64 kg of dry CuCl, and 25 kg of pure pyridine is stirred at 80 °C for 30 min; 750 kg of trichlorobenzene and 150 kg of phthalodinitrile (95 % pure) are then added. The mixture is heated quickly to 200 – 205 °C and stirred for 6 h. The resulting melt can be purified as described above.

The reaction can be accelerated by the use of sodium hydroxide or sulfonic or carboxylic acids [219] instead of pyridine. Other high-boiling solvents such as nitrobenzene, benzophenone, or naphthalene can be used instead of trichlorobenzene [2], [3], [220–223].

The phthalodinitrile – solvent (pyridine) process can be used generally for the production of various metal phthalocyanines and is often suitable when other methods fail. A series of patents cover the low-temperature formation of copper phthalocyanine and continuous processes [3, II, pp. 31 – 32].

Dichlorobenzene Process. Until now, this synthesis [41] has found no use in industry. Heating *o*-dichlorobenzene (50 g) with quinoline (130 g), copper(I) bromide (49 g), and copper(I) cyanide (61 g) at 205 – 220 °C for 4.5 h gives 34.8 g of crude, well-crystallized CuPc (71 % yield) [143, pp. 274 – 278].

Diiminoisoindolenine Process. An alternative route is the formation of the isoindolenines, which are then treated with copper(II) salts [224–226]. 1,3-Diiminoisoindolenine is prepared by reaction of phthalonitrile with ammonia. The isoindolenine is then reacted with copper acetate in ethylene glycol and 2-chlorobenzonitrile at 60 – 70 °C for 1 h. The presence of benzyl cyanide can improve the solvent stability of the pigment [2], [3], [227], [228].

Copper phthalocyanine can also further be made by milling 145 g of diiminoisoindolenine, 24.8 g of copper(I) chloride, 700 g of anhydrous sodium sulfate, and 145 g of ethylene glycol for 3 h at 100 – 110 °C. After slurrying in water, filtration, reslurrying in 1 % hydrochloric acid, and dilution with sodium hydroxide, the product is suitable as a pigment [2][3], [229]. Other solvents and additives are also used for the reaction [230–233].

Production of γ-, δ-, ε-, π-, and X-CuPc. γ-CuPc is obtained by treating the α-modification with 30 % sulfuric acid and glycolmonobutylether at 110 °C [2, 3, 234–236].

δ-CuPc is formed when 25 g of CuPc is dissolved in 250 g of 98 % sulfuric acid and the resulting solution is added to 440 g of benzene, 800 mL of water, and 5 g of turkey red oil at 20 °C over 30 min. After emulsion separation and suspension of CuPc in the benzene layer for 48 h, it is washed with alcohol and water until acid free and dried at 70 °C [237]. Other examples are given in the literature[2], [3], [238].

ε-CuPc is made by mixing 350 g of urea and 295 g of 92 % sulfuric acid in a heavy-duty mixer at 80 °C; adding 400 g of 85 % CuPc made by the phthalic anhydride – urea process; and then adding 1500 g of sodium chloride and 100 g of water. After being mixed for 18 h at 50 – 60 °C the mixture is poured into 17 L of water, boiled, filtered, washed until acid and chloride free, and dried at 60 °C [2], [3]. Other variations are given in [182], [239–243].

π-CuPc is made by refluxing *o*-phthalodinitrile and copper(I) cyanide in 2-(dimethylamino)ethanol and ammonia [2], [3], [91], [92].

X-CuPc is prepared by synthesis of π-CuPc in the presence of a catalytic amount of X-CuPc [93], [94], by ball-milling of the α- and β-forms [95], or by vaporization methods [96].

For toxicological and ecological reasons, some of the solvents used in phthalocyanine synthesis, especially trichlorobenzene, must be replaced. High-boiling hydrocarbons [244–246] or esters [247] have been suggested as replacements. Other processes aim to produce the finished phthalocyanine pigment in order to avoid

the pigment finishing step (Section 4.4). In these processes, syntheses are carried out mostly in polar media (e.g., glycols) at low temperature and often lead to formation of the α-modification [248–253].

4.3.2. Phthalocyanine

Metal-free phthalocyanine has limited production for speciality uses. It is manufactured according to the original ICI process by reaction of phthalodinitrile with sodium amylate and alcoholysis of the resulting disodium phthalocyanine.

Under nitrogen, 20 kg of sodium is dissolved in 800 kg of amyl alcohol; 208 kg of phthalodinitrile is added, and the mixture is heated for 6 h to 125 °C. The Na_2Pc is filtered off, washed with amyl alcohol, and dried under vacuum. The dried and ground Na_2Pc is added to 850 kg of methanol at 5 – 10 °C, whereby metal-free Pc is formed. Stirring is continued until no variation of the sample is visible under the microscope. After dilution with water and filtration through a pressure funnel, washing with methanol and water, and drying under vacuum, H_2Pc is obtained as a powder in 80 % yield.

Phthalocyanine can also be obtained by melting phthalic anhydride and urea in the presence of catalytic amounts of ammonium molybdate [254], [255].

Anhydrous sodium polysulfide can be used instead of sodium alkoxides [256]. An electrochemical process that uses phthalonitrile as starting material in the presence of solvents is described in [257]. Other methods are given in [3, II, p. 29], [258–263], which also deal with production of the crystal modifications.

4.4. Pigment Finishing

Crude phthalocyanine or CuPc is obtained during production in the β-modification. The crystals thus obtained are too large to develop optimal pigment characteristics. They must therefore be subjected to a finishing or conditioning step in which the required modification, having optimal particle size with respect to properties such as color strength, color tone, color purity, grinding, flocculation, and rheology, is formed. Finishing methods are described in [2, p. 152], [264].

The particle size of crude phthalocyanine can be reduced by chemical or mechanical methods. The former involves dissolving phthalocyanine in concentrated sulfuric acid and precipitating it by addition to water. Phthalocyanines with a high halogen content must be treated with oleum or chlorosulfonic acid for purification. Phosphoric acid or sulfonic acids have been also proposed as solvents [2], [3]. The use of dilute sulfuric acid results in formation of a sulfate but leaves the pigment partially undissolved (soaking process). Depending on the sulfuric acid concentration, various sulfates are formed. Hydrolysis of the sulfate formed with 68 % sulfuric acid gives a very finely divided pigment [2], [3], [143]. Sulfates formed at other sulfuric acid concentrations must be ground before hydrolysis. The α-modification of the pigment is obtained by these methods. A variety of patents cover these and other processes [3, II, pp. 35 – 36].

The second finishing alternative involves grinding the dry or humid form, cold or warm, with or without addition of grinding agents such as sodium chloride. Organic solvents, especially aromatic hydrocarbons and their derivatives such as xylene, nitrobenzene or chlorobenzene, alcohols, ketones, or esters can also be used [2], [3]. Grinding is carried out in ball mills or kneaders.

In the absence of solvent, the unrefined pigment in the β-modification is converted to the α-form [2], [3], [264–266]. Figure 4 illustrates the change of particle-size distribution during milling (agglomeration of the primary crystals) and after finishing (deagglomeration and crystal ripening) of the crude pigment in an organic solvent.

Grinding additives such as sodium chloride are removed by boiling with water, and the pigment is isolated by filtration and drying. Little is known about the mechanism by which β-CuPc is ground and simultaneously transformed to the α-modification [264]. In the presence of solvent, this phase transformation is hindered, and a finely divided pigment in the β-modification is obtained.

Figure 4. Particle-size distribution of crude copper phthalocyanine pigment after milling and finishing

4.4.1. Finishing by Treatment with Acid

Dissolving in Acid. Crude product is dissolved in concentrated sulfuric acid and precipitated with water. The degree of agitation and a correct rate of addition are important factors in precipitation [267]. The fineness of the suspension can be improved by addition of emulsifying agents [268], [2, p. 152] or simultaneous use of water-immiscible solvents [269], [2, p. 152], [270].

Hydrophilic agglomeration of pigment particles during drying must be avoided. Otherwise, the pigment may be difficult to disperse later. The tendency to agglomerate increases with decreasing particle size. Agglomeration can be reduced by various additives [2, p. 152] (e.g., ammonium naphthenate) [271], polyalkanolamines of fatty acids [272], nonaqueous solvents [273], or resins [274], [275]. Additives, particularly resins, coat the pigment particles, thereby impeding their agglomeration [276]. Pigments that are easy to disperse are obtained when they are mixed in water and the resin is deposited on the surface of the particles [277], [278].

Production of α-CuPc from Crude CuPc [143, p. 295], [198]. Crude CuPc (700 kg) is added quickly to concentrated sulfuric acid (96 %, 6300 kg), and the temperature is allowed to rise to 50 °C. The suspension is stirred overnight. When the phthalocyanine is completely dissolved, the suspension is sprayed into 35 000 L of water at 70 °C, and the temperature is allowed to rise to 85 – 90 °C. The precipitated pigment is filtered off in a filter press and washed until acid free. The press cake is then mixed with 25 000 L of water, and the remaining acid is neutralized with potassium carbonate and ammonia. After addition of 35 kg of lorol sulfonate the suspension is heated for 1 h until a clear filtrate is obtained. After filtration of the suspension, the press cake is washed with hot water and homog-

enized with sufficient water to give a 20 % paste, which is passed three to five times through a disintegrator (3000 rpm).

Pigment formation by soaking has several advantages compared to dissolution: less sulfuric acid is required, the unrefined phthalocyanine can be processed as a moist press cake, and the resulting pigment has improved color and dispersion properties. To obtain good results, the sulfuric acid concentration must be adjusted within exact limits. An industrial process in which the crude product is allowed to soak in 62 – 72 % sulfuric acid and then hydrolyzed with water [143, p. 294, 304] is carried out as follows:

At 35 °C, 200 kg of CuPc press cake (50 % water) is added to a mixture of 565 kg of 96 % sulfuric acid and 125 kg of ice. The relative density of a filtrate sample should correspond to a sulfuric acid concentration of 68 %. The suspension is stirred for 24 h. Conversion of the β-form to the α-form is monitored by microscopy or X-ray diffraction. Then 6000 L of water is pumped into the suspension. The acid-free washed pigment is again mixed with 2000 L of water. The mixture is made slightly alkaline with ammonia and boiled for 10 min, and the pigment is filtered off and dried under vacuum (14 h at 38 – 40 °C).

A similar soaking process can be used to form the green polychloro CuPc. Because the product is only sparingly soluble in sulfuric acid, it is stirred for 18 – 20 h at 35 – 40 °C in 95 % sulfuric acid, and the sulfate is decomposed at 70 – 93 °C with water.

Conditioning can also be carried out with polyphosphoric acid.

Process Example [279]. One part of crude CuPc is added to seven parts of polyphosphoric acid at 80 – 90 °C. Within 16 h the temperature rises to 195 °C; 30 parts of water (20 – 30 °C) is added, and the mixture is stirred for 2 h. The pigment is isolated by filtration.

For some uses, even a simple hot-water purification may be sufficient [280].

4.4.2. Finishing by Grinding

Finishing by grinding was first described in 1936 [281], [282]. In dry grinding, with salts such as sodium chloride or anhydrous sodium sulfate as grinding agents, the β-modification is converted to the α-modification. The coarse crystals of unrefined material are simultaneously ground to smaller size. Fine particles, high color strength, and good dispersive properties can be obtained when grinding agents are used [283]. Washing out the salts with water gives a color-intensive α-pigment. This procedure has been modified often [3, II, p. 37]. For example, pigment quality is improved by addition of surfactants, dispersants, or resins [2, p. 157], [3, II, p. 37].

The grinding process for β-CuPc is of greater importance than that for α-CuPc production [2, p. 157]. The simplest process involves grinding crude CuPc at 70 °C with a water-soluble salt and small amounts of aromatic or halogenated hydrocarbons or alcohols [2, p. 157], [3, II, p. 37], [284–288].

Process Example [288]. Iron rods (454 kg) of ca. 12.7-mm diameter and 24.4-mm length, crude CuPc (3.6 kg) (chlorine free), aluminum sulfate (22.7 kg), tetrachloroethylene (0.5 kg), and 0.15 kg of a surfactant containing cetyltrimethylammonium chloride are added to a 227-L ball mill. The mill is rotated for 12 h at 70 – 75 % of its critical velocity, and the temperature is allowed to increase to 60 – 70 °C. The charge is then removed and digested with hot, dilute sulfuric acid. A green CuPc pigment with high color intensity and good crystal stability is obtained. X-Ray analysis shows that the pigment is predominantly in the β-form.

Crude CuPc pigment can also be ground in the dry state without grinding aids. A surfactant is often added. This milled product exhibits satisfactory pigment properties only after further treatment in water immiscible organic solvents, for example, which are then removed by distillation after the finishing process is complete [289]. The β-modification of CuPc can also be produced by wet milling in the presence of surfactants [2, p. 157], [290]. Another widely used finishing process is the wet milling of crude pigments in mixers for highly viscous pastes (e.g., kneaders). Dry, crude pigment is kneaded with a water-soluble salt in an organic medium (polyalcohols or polyether alcohols).

Process Example [291]. In a kneader, 283 g of crude CuPc (chlorine free) is ground for 2 h with 1131 g of sodium chloride and 140 g of

poly(ethylene glycol) (M_r=400). Then, 30 g of this paste is boiled in 1 L of water and filtered to remove water-soluble substances. Washing is continued until no trace of water-soluble substance can be found. The moist paste is dried at 70 – 75 °C. A color-intensive β-CuPc is obtained.

A similar finishing process is used for partially or fully halogenated crude pigments. Another process for making an aqueous pigment dispersion involves activating the crude pigment in the presence of a phase-directing solvent (i.e., a hydrophilic agent that activates the pigment surface, facilitating its transfer to the aqueous phase), followed by fine milling in an emulsion containing a second phase-directing solvent [292].

Process Example [292]. A ball mill is charged with 906 g of chlorine-free crude CuPc and 45 g of turpentine and then rotated for 24 h at 70 % of the critical speed. An emulsion is produced by stirring 160 g of water, 12.5 g of turpentine, and 2.8 g of Aerosol OT (75 %) in a laboratory attritor for 2 – 3 min. At 375 rpm, 40 g of milled crude CuPc is added to the emulsion, and the water and turpentine are separated from the pigment slurry by filtration through a screen. The slurry is then added to 1 L of water containing sufficient hydrochloric acid to yield a pH of 1 – 2. After being heated to 75 – 90 °C for 30 min, the slurry is filtered, washed acid free, and dried.

4.5. Stabilization of Phthalocyanines

Unsubstituted and halogenated phthalocyanine and copper phthalocyanine possess a few principal disadvantages for industrial applications [2, p. 344], [125], [264]. In pure form they are extremely hydrophobic solids (Chap. 2.5) and therefore tend to flocculate in binders and paints [70], [73], which results in reduction of the color strength and poor flow properties of the dispersions. This effect is particularly apparent in combination with titanium dioxide [125]. The process can be observed by optical and electron microscopy [293]. A review with emphasis on CuPc and titanium dioxide in nonpolar media is given in [294]. A further disadvantage, especially of unchlorinated α-CuPc, is its instability in organic solvents, where conversion into the β-modification and formation of coarse crystals can occur [2, p. 165], [264].

These deficiencies are eliminated by various means. Unstable modifications, mainly the α-form of CuPc, can be stabilized by partial chlorination [2, p. 165]. Chlorine atoms in the 4-position are much more effective than those in the 3-position [170]. Partial sulfonation of CuPc increases flocculation stability. A combination of both methods leads to a high-quality pigment, particularly for solvent- containing coatings [2, p. 165]. Another method is to add phthalocyanines of tin, vanadium, aluminum, or magnesium [2, p. 165]. The addition of CuPc derivatives has also become important. These additives introduce new adsorption centers on the pigment surface. Monomeric and polymeric derivatives with basic substituents are, for example **18** [295] and **19** [296], [297].

18, $n = 1-8$ **19**, $x \geq 2$

These molecules are very strongly adsorbed on the surface of the pigment, thus fixing basic centers that promote the adsorption of binder molecules. The colloid stability is due to the adsorbed layer of binder [122], [124], [276]. The addition of CuPc derivatives with long aliphatic chains gives pigments that also show high flocculation stability in the absence of polymers in aliphatic hydrocarbons [298]. Other additives are derived from the amides or salts of CuPc sulfonic acids [299–302].

These additives also strongly hinder recrystallization of the pigments and can therefore be used to stabilize unstable modifications such as the reddish, chlorine-free α-CuPc [303–306]. Other methods involve the use of surfactants [307–310] or adsorbed resin layers [311].

5. Phthalocyanine Derivatives

The copper phthalocyanine derivatives are of major industrial importance as green organic pigments (halogenated products) and dyes. The first pigments of this class were commercialized

in 1938. The first phthalocyanine dye was polysulfonated CuPc [42]. Since then, many patents describing various phthalocyanine compounds have been registered [1]. Substituted phthalocyanines are either accessible through synthesis from phthalocyanine derivatives (with the advantage of defined products) or through substitution of phthalocyanines [1, p. 255], [2, pp. 171, 192]. The latter method is favored in industry for economic reasons.

Synthesis. Usually 4 mol of a substituted phthalodinitrile or a substituted phthalic acid is used as starting material. A mixture of an unsubstituted and substituted starting material in approximate ratios, respectively, of 1:3, 2:2, or 3:1 can also be used. When reactivities of the two starting materials are approximately equal, Pc derivatives whose degree of substitution closely corresponds to the ratio of the starting materials are obtained. More often, however, a mixture of products results.

With the exception of tetrachlorophthalic acid, substituted phthalic acids, phthalimides, or phthalonitriles are industrially not readily accessible in pure form. Therefore, synthesis from phthalic acid derivatives is used only when the substitution reaction fails. For example, tetranitrophthalocyanines can be synthesized from 4-nitrophthalimide, whereas direct nitration of phthalocyanines gives only the oxidation products. Other substituted copper phthalocyanines such as tetra-4-phenyl copper phthalocyanine cannot be produced by direct introduction of the desired substituents.

Substitution. Copper phthalocyanine is preferred as starting material. Very little is known about the position of substitution. With the exception of hexadecachloro CuPc, all commercial Pc substitution products, as well as the tetrasubstituted derivatives synthesized from monosubstituted phthalic acids, are mixtures of isomers. Despite the 16 hydrogen atoms that can be substituted, only two different monosubstituted Pc's are possible. The number of disubstituted isomers is higher. Mono- to heptasubstituted Pc derivatives have not yet been isolated in isomerically pure form. In addition, only a limited number of isomers are accessible in pure form by synthesis. Only symmetrically substituted phthalic acids, phthalimides, or phthalodinitriles (3,6-di-, 4,5-di-, or 3,4,5,6-tetrasubstituted derivatives) yield pure isomers of octa- or hexadecasubstituted phthalocyanine derivatives. All other substituted phthalic acids give mixtures of isomers.

5.1. Halogenated Phthalocyanines

Perchloro and perchlorobromo copper phthalocyanines are of major industrial importance as green organic pigments with high lightfastness. Commercial development of these pigments began in 1935 [312], [313]. They are obtained by direct chlorination of copper phthalocyanine. The color changes only slightly from blue to green with the introduction of the first five to seven chlorine atoms, but a strong change in color occurs when the tenth to fourteenth chlorine atoms are introduced. Introduction of the last two chlorine atoms does not influence the shade. Replacement of chlorine by bromine displaces the color from blue to yellowish green [314]. These products were first marketed in 1959 [315]. Because the introduction of 15 to 16 bromine atoms is very difficult, commercial yellowish CuPc pigments thus contain 11 to 12 bromine atoms and 4 to 5 chlorine atoms per molecule. The halogenated derivatives are prepared by direct chlorination of copper phthalocyanine in a eutectic melt of aluminum and sodium chloride [143], [205], [313].

Hexadecachloro Copper Phthalocyanine [316]. In a 2.4-m^3 vessel equipped with a stirrer, 1800 kg of aluminum chloride and 420 kg of sodium chloride are heated to give a homogeneous melt; the temperature rises to 160 °C. The temperature is lowered to 100 – 110 °C in 1 – 2 h by external cooling; then 600 kg of CuPc is added over a period of 1 h. Chlorine is introduced initially at a rate of 30 kg/h, which is increased to 50 kg/h after 30 min and then to an average rate of 100 kg/h when addition of CuPc is complete. The temperature is kept below 150 °C by external cooling and regulation of the chlorine flow rate between 80 and 120 kg/h. The chlorine flow is stopped when the required degree of chlorination is attained (normally after 11 – 13 h). The melt is then heated to 180 °C, held at this temperature for 30 min, and

discharged into water. The polychlorophthalocyanine is isolated from the aqueous suspension. The yield is 1100 kg, with a chlorine content of 48 – 49 %. The aluminum content is < 0.05 %.

When CuPc is halogenated with bromine instead of chlorine in an $AlCl_3$ – NaCl melt in the presence of copper(II) chloride, a polybromo-CuPc is obtained that contains eleven bromine atoms and three chlorine atoms. A further development of the procedure includes the addition of sulfur trioxide or chlorosulfonic acid [317] and sulfur dichloride to the melt [318].

Low-melting complexes of aluminum trichloride with SO_3, $SOCl_2$, or SO_2Cl_2 can also be used as reaction media for the perchlorination of phthalocyanines, particularly CuPc, at 60 –200 °C. Especially significant is that on decomposition of this chlorination melt, perchlorinated CuPc precipitates in a form that does not require recrystallization from sulfuric acid [319].

Inorganic acids such as sulfuric or phosphoric acid are unsuitable solvents for chlorination because they lead to partial oxidative degradation of CuPc.

Organic solvents such as tri- or tetrachlorobenzene, acid chlorides, carbon tetrachloride, or nitrobenzene are also less suitable for halogenation of phthalocyanines [2, pp. 171, 192]. Only perchlorocyclopentene and perchloroindane have proved suitable [320]. Chlorination in molten phthalic anhydride or its chlorinated derivatives leads to complete chlorination of phthalocyanines. Chlorination of metal-free phthalocyanine (e.g., in phthalic anhydride) up to a content of about 12 chlorine atoms gives a yellowish green pigment [143]. Chlorination of CuPc in the absence of solvents is possible at 200 – 250 °C; the crude CuPc can be diluted with salts [321], [322].

Synthesis from chlorinated phthalic anhydride gives the α-modification of copper phthalocyanine derivatives directly. Either 4-chlorophthalic anhydride and urea or phthalodinitrile is used as starting material under conditions that lead to partial chlorination [323], [324]. The crude product often contains some of the β-modification, which is converted to the stable α-modification during pigment finishing.

Fluorinated phthalocyanines are also known [325], [326]. Hexadecafluorophthalocyanine can be prepared from tetrafluorophthalocyanine [203]. These products have surprising properties; for example, they are soluble in many organic solvents.

Halogenated phthalocyanines must be converted to useful pigments by finishing (Section 4.4). Solvents such as methanol, butanol, ethylene glycol, triethanolamine, esters of aliphatic and aromatic carboxylic acids [327], mixtures of aliphatic ketones and water, [328] or benzoic acid [329] are used as finishing agents.

5.2. Phthalocyanine Sulfonic Acids and Sulfonyl Chlorides

The sulfonic acids and sulfonyl chlorides, especially those of CuPc, are readily accessible. The sulfonic acids, $CuPc(SO_3H)_n$ with n=2, 3, or 4, were significant direct cotton dyes (C.I. Direct Blue 86, 74 186 and 87, 74 200). The sulfonyl chlorides are intermediates in the production of various copper phthalocyanine colorants [1, p. 259], [2, p. 192]. The watersoluble sulfonic acids are produced by heating copper phthalocyanines in oleum. By varying concentration, reaction temperature, and time, one to four sulfo groups can be introduced in the 4-position [330]. The products synthesized from 4-sulfophthalic acid exhibit slightly different properties. This is due to the different isomer distribution with respect to the 4- and 5-positions. Only one sulfo group is introduced in each benzene ring, as shown by the fact that only 4-sulfophthalimide is obtained on oxidative degradation. The most important dyes have two sulfonic acid groups per molecule and are prepared as follows:

Copper Phthalocyanine Disulfonic Acid [205]. Within 1 h, 150 kg of CuPc (97 – 98 % pure) is added to 1200 kg of 26 % oleum, with the temperature kept below 45 °C. The mixture is heated for ca. 12 h at 60 – 61 °C. The reaction is complete when a sample is fully soluble in dilute soda solution and the addition of sodium sulfate does not lead to any precipitation [198, p. 59]. The solution is then stirred into a mixture of 5000 L of saturated sodium chloride solution and 4000 kg of ice. The suspension is brought to 30 000 L with cold water and filtered through a filter press. The press cake is dried inside an air-circulating oven at 60 – 70 °C and then ground with soda.

Partially sulfonated cobalt phthalocyanine, which is an important dye (C.I. Vat Blue 29, 74 140), is prepared in a similar manner [331]. The corresponding disulfonic acid is used as an oxidation catalyst (Section 3.3). The cobalt [332], nickel [333], iron [334], chromium [335], manganese [336], and zinc [336] phthalocyanine sulfonic acids are synthesized by the urea process from 4-sulfophthalic acid.

The sulfonyl chlorides are prepared directly from chlorosulfonic acid and phthalocyanines [337]. Some of the sulfonyl chloride groups are hydrolyzed by the water formed in the reaction. Nearly pure phthalocyanine sulfonyl chlorides are obtained when phosphorus tri- or pentachloride or thionyl chloride is added. The positions of the sulfonyl chloride groups are the same as those of the sulfonic acids [330].

Copper Phthalocyanine Tetrasulfonyl Tetrachloride [338]. To 1500 parts of chlorosulfonic acid is added 193 parts of CuPc within 1 h. The mixture is heated 1 h to 70 – 75 °C, in 1.5 h to 75 – 130 °C, and for 4 h at 130 – 135 °C. The brown color of the starting material changes to green. After being cooled to 80 °C, 600 parts of thionyl chloride is slowly added and the mixture is stirred for 1 h at 75 – 80 °C. The solution is stirred into ice; the sulfonyl chloride is filtered off and washed with water. The tetrakis(3-sulfonyl chloride) is free of sulfonic acid groups.

A broad range of sulfonamide dyes are accessible by substitution of CuPc sulfonyl chlorides with amines. Dyes thus obtained can be used in nearly all fields of dyeing [1, p. 259], [2, pp. 171, 192].

5.3. Chloromethylphthalocyanines

After sulfonic acid chlorides, the chloromethyl derivatives constitute the second most important group of phthalocyanine derivatives. Like acid chlorides, they can be converted to a wide range of colorants by reaction with amines or phenols. In the original procedure [339] introduced by Haddock and Wood, the chloromethyl compounds are formed by substitution of phthalocyanines with bis(chloromethyl) ether in the presence of aluminum chloride and tertiary bases such as triethylamine or pyridine. Up to eight chloromethyl groups can be introduced. Another procedure involves the substitution of phthalocyanines with paraformaldehyde in sulfuric acid or chlorosulfonic acid [340]. Since bis-(chloromethyl) ether is carcinogenic [341], the reaction must be carried out in a hermetically sealed apparatus. Dichloromethyl ether is also produced in synthesis from paraformaldehyde in the presence of substances such as chlorosulfonic acid that produce hydrochloric acid.

5.4. Phthalocyanines with Other Substituents

Other phthalocyanine derivatives with various substituents, represented by formula **20**, are known for R=*tert*-butyl [342–346]; NR_2 [346–348]; OR [343], [344], [349–354]; SR [355], [356]; SiR_3 [343], [344]; CF_3 [357]; SCF_3 [358]; SO_2NR_2 [359–361]; COOH [362–366]; COOR [367], [368]; CN [347], [369–371]; NO_3 [372], [373]; and OH [374]. These derivatives are greener and more turbid than the copper phthalocyanines. More details and further references can be found in [1, p. 255], [2, pp. 192, 308].

20

5.5. Polymeric Phthalocyanines

Combination of a phthalocyanine with a polymer or incorporation of a phthalocyanine into a polymer matrix is a powerful tool for designing new materials with special properties. Polymer phthalocyanines are of interest as catalysts, semiconductors, and lubricants because they are more stable than the corresponding monomers.

The following principles are used to form phthalocyanine polymers:

1) Linking through the central metal atom as part of the polymeric chain [30–35]
2) Linking of neighboring phenyl rings (diphenyl structure)
3) Linking through substitution (e.g., ether bridges, ethylene bridges)

4) Linking through phenyl rings that belong to two phthalocyanine systems
5) Linking of the phthalocyanines to a polymer chain
6) Linking the metal of a phthalocyanine with a polymer donor ligand, or electrostatic bonding of a charged phthalocyanine with a charged polymer chain

Details of the polymeric phthalocyanines are given in [1, pp. 274 – 275], [2, p. 328], [3, II, p. 91], [375, pp. 59 – 125].

5.6. Phthalocyanine Analogues

Phthalocyanine analogues include compounds such as porphyrins (**8**, Chap. 1), in which the four pyrrole rings are linked through one to four aza bridges and up to eight β-hydrogen atoms of the pyrrole are substituted [2, p. 308], [3, I, p. 195]. Like the phthalocyanines, many of these compounds exhibit very low solubility and are therefore potential pigments. Many such derivatives have been synthesized and studied. Because of their high cost and various application problems, none of these products have found use in industry.

Replacement of Benzo Rings by Other Ring Systems. The four benzo rings of phthalocyanines can be replaced by other aromatic ring systems such as naphthalene or aromatic heterocycles, for example, **21**–**27**.

21

22

23

24

These compounds are derived from the corresponding *o*-dicarboxylic acids, their anhydrides, or *o*-dinitriles. The naphthalophthalocyanines (**21**) [376], their derivatives, [377], [378], and their metal complexes show reactions similar to phthalocyanines [13], [379]. The analogue **22** is redder than phthalocyanine [143, pp. 334 – 336], [380], and **23** is redder still but also more turbid [143, pp. 334 – 336], [381]. These are the reddest phthalocyanine analogues known. The tetrathiophenotetraazaporphyrin **24** has a greenish color [382]. Crown ether derivatives (**25**) [383–385] and cumyl phenoxy derivatives [386] have also been reported. Octaphenyl Pc's (**26**) and analogues **27** [387] have been prepared from the corresponding diphenyls and dicyanotriphenylenes. An anthracene analogue of Pc is prepared from 2,3-dicyano-9,10-diphenylanthracene [388].

25

26

27

Derivatives of Tetraazaporphyrin. Alkyl and aryl derivatives of tetraazaporphyrin (**28**) such as tetramethyltetraazaporphyrin (**28**,

R=CH_3, R′=H) [389], octamethyltetraazaporphyrin (**28**, R=R′=CH_3) [390–392], and octaphenyltetraazaporphyrin (**27**, R=R′=C_6H_5) [393–395] belong to this group.

28

Hexadecahydrophthalocyanine can also be included in this group [177], [396]. The copper complexes of hexadecahydrophthalocyanine are among the reddest phthalocyanine analogues known. Starting materials for the latter two derivatives (the dialkylmaleic anhydride or dinitrile) [397] are not readily accessible; therefore these compounds are not in industrial use. Tetra- and octaphenyltetraazaporphyrins and their alkyl derivatives are potential oil-soluble dyes and siccatives [398–400].

Other Aza- and Thiaporphyrins. Metal complexes derived from mono-, di-, or triazatetrabenzoporphyrin or thiatetrabenzoporphyrins (**29**) are greener and more turbid than CuPc. They have no industrial importance. Tetrathio Pc's (**30**) are more strongly colored than the corresponding Pc's themselves [401–403].

29

30

6. Legal Aspects and Environmental Protection

Although CuPc pigments exhibit very low toxicity, producers and users are faced with various regulatory changes, which are related to the presence of copper in these substances [404], [405].

Since the inhalation of dusts and mists of copper salts can result in irritation of nasal mucous membranes, OSHA has established PEL of 0.1 mg/m^3 for copper fumes, and 1 mg/m^3 for dusts and mists of copper salts [405]. The German TA Luft calls for 5 mg/m^3 Cu in off-gases. The MAK value for copper is 1 mg/m^3 [341]. The issue of copper in wastewater is more complex because concerns are based on the toxicity of soluble copper to various aquatic species. The EPA ambient water criteria for copper call for a 4-day average of 12 µg/L (1 day max. 18 µg/L), whereas the maximum contamination level of copper for public drinking water is 1 mg/L [406]. Thus, the 12 – 18-ppb copper in wastewater from CuPc production may be a problem and is handled by authorities on a case-by- case basis. Regulations in Germany call for 0.2 – 0.3 mg/L Cu in wastewater.

A method for removing copper(II) ions from wastewater in CuPc production is treatment with hydrosulfite to give a copper concentration of < 1 mg/L [407]. Another possibility is the addition of MoO_3, then the precipitation of molybdenum with a high molecular mass amine, and finally copper flotation with alkylxanthogenate [408]. The Resource Conservation and Recovery Act (RCRA; USA) of 1976 and the Hazardous and Solid Waste Amendments (HSWA; USA) of 1984 regulate the generation, transportation, treatment, storage, and disposal of hazardous and nonhazardous waste. Copper-containing waste is classified as nonhazardous under RCRA [405]; other regulations apply only to soluble or bioavailable copper, not to CuPc pigments. For the production of other metal phthalocyanine pigments, similar treatment of wastewater, off-gas, solid, and liquid waste; transportation; storage; and disposal involving the regulations must be taken into account, especially with respect to bioavailable metals.

Polychlorinated biphenyls (PCBs) have been detected in pigments manufactured in trichlorobenzene but not in those made with nonchlorinated solvents [409].

7. Quality Specifications and Analysis

Several procedures are applied to the testing of phthalocyanines. Tests for crystallization, flocculation, and applications in paints, plastics, and printing inks have been standardized [3, II, pp. 109 – 119].

Crystallization tests are carried out in xylene or in various paints [410], [411]. The flocculation test follows the ASTM standard specification for copper phthalocyanine [412]. This specification covers CuPc blue pigment in dry powder form for use in paint, printing ink, and related products. Tests include pigment composition, color, character of tint, oil absorption, reactions in identification tests, and dispersion and storage stability of the end product. Application tests for printing inks, paints, and plastics are described in [3, II, pp. 112 – 115], [412].

Identification methods consist of the trichloroacetic acid test [413], the N.P.I.R.I. standard test for pigment identification [414], and tests for various applications.

Quantitative determinations of the pigment are possible with cerium(IV) sulfate [10] or sodium vanadate [415]. Copper and chlorine determinations are often important [416].

8. Uses

Phthalocyanines are used predominantly (ca. 90 %) as pigments. These pigments are almost always copper phthalocyanines or their halogenated derivatives. This group of pigments accounts for 25 % of the total organic pigment capacity. Worldwide consumption of organic pigments in 1989 was estimated to be 250×10^3 t. Modification of the nearly insoluble phthalocyanines by introduction of various substituents has led to the use of Pc's as dyes for textiles, paper, and leather or as specialty dyes (e.g., for ballpoint pen inks). The colors of these dyes range from brilliant blue through turquoise to green. Phthalocyanine dyes are therefore used in almost all cotton dyes, synthetic-fiber dyes, sulfur and azo developing dyes, and reactive dyes.

8.1. Phthalocyanine Pigments

Because of their excellent color properties and high fastness to light, weathering, and various solvents, phthalocyanine pigments are used in nearly all fields. Furthermore, they are less expensive than other organic pigments. Phthalocyanine pigments are particularly important for gravure, offset, and flexo printing. The β-form of copper phthalocyanines is used predominantly in this field. Other important applications are in the paint, coating, plastics, textile, and spin-dyeing industries. Through special procedures during finishing of the crude pigment, optimal pigments are produced for each application. The use of additives leads to improved rheological properties and reduced flocculation. Apart from pure pigment powders, preparations are manufactured in which the pigment is already dispersed in a suitable binder system (e.g., polyethylene, nitrocellulose, polyamide, or liquid systems). The range of phthalocyanine products is now very large. For example, the Heliogen trademarks (powder pigments) of BASF include 48 products, of which 13 are the α-modification, 22 the β-modification, 2 the ε-modification, 1 is metal free, and 10 contain halogen.

Phthalocyanine pigment producers and trade names are as follows:

American Cyanamid, USA	Cyan Blue, Cyan Green
Aziende Colori Nazionali Affini, Italy	Turchese Segnale Luce, Verde Segnale Luce
BASF, Germany	Heliogen-Blau, Heliogen-Grün
Bayer, Germany	Helioecht-Blau, Helioecht-Grün
Ciba-Geigy, Switzerland	Irgalith-Blau, Irgalith-Grün
Dainichi Seika Colors, Japan	Chromofine Blue, Chromofine Green
Dainippon Ink and Chem. Co., Japan	Cyanine Blue, Cyanine Green, Fastogen Blue, Fastogen Green
Du Pont, USA	Cinquasia Blue, Cinquasia Green
Harmon Colors-National Aniline Division, USA	Phthalo-Blue, Phthalo-Green
Hilton Davis Chemical Co., USA	Peacoline Blue
Hoechst, Germany	Hostapermblau, Hostapermgrün
ICI, UK	Monastral Blue, Monastral Green
Kemisk Vaerk Koge, Denmark	Isophthalblau, Isophthalgrün
Produits Chimiques Ugine Kuhlmann, France	Cyanine Lutetia, Emerande Lutetia
Sandoz, Switzerland	Sandorin-Blau, Graphtol-Blau, Graphtol-Grün
Sumitomo Chemical Co., Japan	Sumitone Cyanine Blue, Sumitone Cyanine Green
Sun Chemical Co., USA	Fastolux Blue, Fastolux Green

Further information about manufacturers and trade names can be found under Pigment Blue 15, 74 160, in the Colour Index.

15 unstable α-CuPc
15:1 crystalline, stable α-CuPc
15:2 crystalline, stable, nonflocculating α-CuPc
15:3 β-CuPc
15:4 nonflocculating β-CuPc
15:6 ε-CuPc

C.I. Pigment Blue 16, 74 100 is metal free.

C.I. Pigment Green 7 is 74 260; C.I. Pigment Green 36, 74 265.

8.2. Phthalocyanine Dyes

The first phthalocyanine dye was a sulfonic acid derivative, synthesized in 1929 [42]. These dyes are still in use today to dye cotton. The sodium salts of copper phthalocyanine disulfonic acid (C.I. Direct Blue 86) and trisulfonic acid (C.I. Direct Blue 87) and their derivatives are also used. C.I. Acid Blue 185 is a wool dye. Finishing additives such as Solidogen (Hoechst) or Levogen (Bayer) improve the wetfastness of these CuPc sulfonic acids. Further applications are leather and paper dyeing.

Brilliant dyes that are readily soluble in alcohols and glycol ether can be obtained by reaction of Pc sulfonyl chlorides with amines. In addition to sulfonamide groups, these dyes contain ammonium sulfonate substituents. They can be used to color transparent paint, flexo and gravure printing ink, wood stains, plastics, and ballpoint ink. Commercial products include C.I. Solvent Blue 24, 74 380 and C.I. Solvent Blue 42, 44, 46, and 52. Substitution of copper phthalocyanine sulfonyl chlorides with primary amines that also contain a tertiary or secondary amino group leads to dyes that are soluble in acidic media. They are used mostly for printing ink, ballpoint ink, ink ribbons, copying ink, and carbon paper. Commercial products include Astrablau 6 GLL (Bayer) and Blaubase KG (BASF).

In addition to these widely applicable phthalocyanine dyes, a number of specialty dyes are used in the textile industry. In one case, functional groups are introduced into the phthalocyanine molecule, which solubilize the compound and are later cleaved on the fiber by further treatment. For example, the Inthion dyes (Hoechst) have thiosulfate esters in the side chains that are cleaved during the dyeing process [417].

The reaction of trichloromethyl copper phthalocyanine with tetramethylthiourea gives an isothiuronium salt, whose hydrophilic groups can be cleaved by weak bases [418]. Trade names can be found under C.I. Ingrain Blue 1, 74 240 (e.g., Alican Blue 8 G, ICI). Another possibility is linking a copper or nickel phthalocyanine derivative with a reactive group on the fiber (e.g., via sulfo groups) [419]. Commercial products of this type are listed in [420]. Examples are the copper phthalocyanine derivatives C.I. Reactive Blue 7, 74 460 (e.g., Cibacron Turquoise Blue, Ciba Geigy; Procion Turquoise MX-G, ICI; Remazol Turquoise Blue, Hoechst; Levafix Turquoise Blue E-G, Bayer; Primazin Turquoise Blue, BASF and nickel phthalocyanine derivatives such as Remazol Brilliant Green 6 B (Hoechst) and Cibacron Turquoise Blue (Ciba Geigy).

In contrast to the above-mentioned dyes, phthalocyanine developing dyes do not contain any substituents. They thus give purer, more genuine colors. Details of manufacturing, composition, and applications are given in [202], [421].

The phthalocyanine is generally synthesized from an isoindolenine or its derivative and a metal compound by drying and subsequent heating to 120 °C. The starting materials are impregnated in the fibers with water-soluble solvents such as glycol and diglycol monoethyl ether or diethanolamine. The solvents and additives act as reductants [421]. Important products are C.I. Ingrain Blue 2:1, 74 160 (e.g., Phthalogen Brilliant Blue IF 3 GM, Bayer and Sumilogen Brilliant Blue, Sumitomo). Other products include Phthalogen Turquoise 3 FBM and Phthalogen Marine Blue IRRM (Bayer).

Phthalocyanine dye producers and trade names are as follows:

American Cyanamid, USA	Calcomine Turquoise, Calcotone Green
Aziende Colori Nazionali Affini, Italy	Segnale Light Green, Eliama Light Turquoise
BASF, Germany	Lurantin Light Blue, Blaubase KG, Primazintürkisblau
Bayer, Germany	Astrablau, Sirius Supra Turquoise
Ciba Geigy, Switzerland	Chlorantine Fast Turquoise, Pergasol Turqoise Blue
Dainippon Ink and Chem. Co., Japan	Daivougen Blue, Symulon Turquoise, Fastogen Blue, Fastogen Green
Du Pont, USA	Pontamine Fast Turquoise, Brilliant Bond Blue
Hilton Davis Chemical Co., USA	Hiltamine Turquoise Blue
Hoechst, Germany	Remazol Turquoise Blue, Hostaperm Green
ICI, UK	Durazol Blue, Alican Blue, Monosol Blue
Sandoz, Switzerland	Pyrazol Turquoise, Cuprofix Blue, Finisol Blue Green
Sumitomo Chemical Co., Japan	Sumilight Supra Turquoise, Sumilogen Brilliant Blue

Further information can be found in the Colour Index:

C.I. Ingrain Blue 2:1, 74 160	developing dyes
C.I. Direct Blue 86, 74 180	CuPc disulfonate salt
C.I. Direct Blue 87, 74 200	CuPc trisulfonic acid
C.I. Ingrain Blue 3, 74 280	diiminoisoindolenine precursor of copper tetraphenylphthalocyanine
C.I. Solvent Blue 24, 74 380	CuPc, sulfonated
C.I. Reactive Blue 7, 74 460	CuPc tetrasulfonic acid containing 1 amide and 1 sulfophenylamide group

9. Economic Aspects

World capacity for crude phthalocyanine in 1987 was estimated at ca. 56 500 t [422]. Capacity in tonnes by geographic area is

North America	
United States	4 700
Mexico	750
South America	
Brazil	700
Argentina	250
Venezuela	250
Western Europe	
Germany	4 500
United Kingdom	3 100
France	2 000
Italy	3 700
Switzerland	200
Eastern Europe	3 000
Far East, Oceania	
Japan	18 000
India	3 400
South Korea	6 500
Taiwan	3 700
Thailand	300
China	1 000
Australia	400
Total	56 450

The major world producers are listed in Table 1. The producers were operating at ca. 80 % of capacity in 1989.

In the 1980s, only one new company in the United States began producing intermediates while many have dropped out. The greatest growth in intermediate production today is took place in India, Korea, and Taiwan, and these countries are likely to become even more significant producers [422].

Figure 5 shows the capacity distribution according to geographical regions; 59 % of the capacity is concentrated in the Far East. World capacity in the year 2000 is expected to reach 75 000 t.

Table 1. Major producers of crude phthalocyanine

Company	Location	Estimated 1989 capacity, t
Toyo/Cosmos	Japan, Taiwan	9000
DIC/Sudarshan	Japan, India	8000
Ciba Geigy	United Kingdom, Switzerland, Korea	4500
Phthalchem	United States	4500
BASF	Germany, Brazil	4500
Acna	Italy	3500
Woo Song	South Korea	3000
DNS	Japan	3000
ICI	United Kingdom, France	2000
Sigma	Taiwan	1500
Maintop	Taiwan	1000
Sanyo	Japan	1000

Figure 5. Production capacity for crude phthalocyanine according to geographical regions

Table 2. Consumption data for phthalocyanines (1989)

Application	Estimated consumption, t
Printing ink	19 500
Paint	9 500
Plastics	8 000
Textiles	3 000
Dyes	2 000
Specialty uses	2 000

Consumption data for phthalocyanines in paint, printing ink, plastics, textiles, dyes, and specialty uses (leather, paper, ballpoint ink) are listed in Table 2.

10. Toxicology and Occupational Health

Copper phthalocyanine pigments have found widespread acceptance because of their durability, excellent color, and good working properties. Adding to their attractiveness is the fact that Pc pigments are insoluble in water and lipids. No substantial scientific evidence exists to indicate that Pc pigments pose a significant risk to human health in the workplace or to the environment [404].

Acute Toxicity Tests. The CuPc pigments have LD_{50} values of > 10 g/kg in rats, which is more than 40 times less toxic than CuO or 70 times less toxic than $CuCl_2$ [404], [405]. The LD_{50} values were confirmed for the following CuPc pigments: phthalocyanine Blue 15 and Green 7 [423]. Doses of CuPc sulfonate up to 100 mg/kg in mice, guinea pigs, rabbits, cats, and dogs did not induce any toxic effects [424]. At concentrations of 5000 ppm, two commercial CuPc sulfonates were nontoxic to protozoans, small crustaceans, small fish, and, when injected, to rabbits, rats, and guinea pigs [425]. Skin and eye irritation studies [426] on CuPc and the Ames tests for mutagenicity were negative [427].

Chronic Toxicity Tests. No carcinogenic risk to humans was indicated in a study of laboratory mice, in which tumors failed to develop over an eight-month period [428]. A subchronic feeding study using doses up to 5000 mg/kg of body weight did not reveal any toxicity or pathological changes related to the Pc pigments administered [405]. The National Toxicity Program in the United States canceled a long-term bioassay on Pc's, because a 13-week feeding study of mice and rats did not indicate any toxicity [429]. Based on the very low solubility of the pigments in aqueous and nonaqueous media and the conclusion of nonbioavailability to humans, testing of a chemical fate and ecological effects of Pc green pigment was suspended by the TSCA Interagency Testing Committee. The FDA has approved the use of copper Pc in general and opthalmic surgery (e.g., for coloring polypropylene sutures, foils, and packaging), for contact lenses, and for food packaging [406]. The MAK value of copper in fumes is 0.1 mg/m^3 and in dust 1 mg/m^3. The TLV value for copper dust is 1 mg/m^3, which corresponds to 10 mg/m^3 CuPc [430] because the copper content of CuPc is usually <12 %. A Russian study recommends a maximum permissible concentration of 5 mg/m^3 in the workplace [431]. Workplace exposure can readily be reduced to meet these limits through engineering controls and protective equipment [404].

Studies of the uptake of sulfonated phthalocyanines (Ni, Zn, Cu, Co, Al) by cultured mammalian cells [432] and chick embryos [433] point to possible teratogenic effects. However, control experiments with copper(II) chloride suggest that at high concentrations copper is responsible for these findings rather than sulfonated phthalocyanine.

1. Introduction

Hans G. Völz

1.1. General Aspects

Definition. The word “pigment” is of Latin origin (pigmentum) and originally denoted a color in the sense of a coloring matter, but was later extended to indicate colored decoration (e.g., makeup). In the late Middle Ages, the word was also used for all kinds of plant and vegetable extracts, especially those used for coloring. The word pigment is still used in this sense in biological terminology; it is taken to mean dyestuffs of plant or animal organisms that occur as very small grains inside the cells or cell membranes, as deposits in tissues, or suspended in body fluids.

The modern meaning associated with the word pigment originated in this century. According to accepted standards (Table 1, “Coloring materials: Terms and definitions”), the word pigment means a substance consisting of small particles that is practically insoluble in the applied medium and is used on account of its coloring, protective, or magnetic properties. Both pigments and dyes are included in the general term “coloring materials”, which denotes all materials used for their coloring properties. The characteristic that distinguishes pigments from soluble organic dyes is their low solubility in solvents and binders. Pigments can be characterized by their chemical composition, and by their optical or technical properties. In this introductory chapter, only inorganic pigments used as coloring materials are discussed.

Table 1. Listing of standards for pigments

Keywords	ISO	EN	ASTM	DIN
Acidity/alkalinity	787–4		D 1208	ISO 787–4
Aluminum pigments and pastes:				
Sampling and testing			D 480	55 923
Specifications	1247		D 962	55 923
Barium chromate pigments:				
Specification	2068			
Bleeding	787–22	14463–4	D 279	EN 14463–4
Carbon black pigments (see also lampblack):				
Ash Content				53 586
Black value				55 979
Solvent-extractable material			D 305	55 968
Specification			D 561	55 968
Cadmium pigments:				
Specification	4620			
Chalking degree:				
Adhesive tape method	4628–6	ISO 4628–6		EN ISO 4628–6
KEMPF method			D 4214	53 159
Photographic method			D 659	
Velvet method	4628–7	ISO 4628–7		EN ISO 4628–7
Change in strength (see ease of dispersion and				

PVC)

Extenders (fillers) are substances in powder form that are practically insoluble in the medium in which they are applied. They are usually white or slightly colored, and are used on account of their physical or chemical properties. The distinction between an extender and a pigment lies in the purpose for which it is used. An extender is not a colorant, it is employed to modify the properties or increase the bulk (volume) of a given material. For further details, see ⟶ Paints and Coatings; ⟶ Paper and Pulp – Fillers; and ⟶ Plastics, Additives – Fillers and Coupling Agents.

History. Natural inorganic pigments have been known since prehistoric times. Over 60 000 years ago, natural ocher was used in the Ice Age as a coloring material. The cave paintings of the Pleistocene peoples of southern France, northern Spain, and northern Africa were made with charcoal, ocher, manganese brown, and clays, and must have been produced over 30 000 years ago. About 2000 B.C., natural ocher was burnt, sometimes in mixtures with manganese ores, to produce red, violet, and black pigments for pottery. Arsenic sulfide and Naples yellow (a lead antimonate) were the first clear yellow pigments. Ultramarine (lapis lazuli) and artificial lapis lazuli (Egyptian blue and cobalt aluminum spinel) were the first blue pigments. Terra verte, malachite, and a synthetically prepared copper hydroxychloride were the first green pigments. Colored glazes for bricks (i.e., ceramic pigments) were widely used by the Chaldeans. Calcite, some phases of calcium sulfate, and kaolinite were the white pigments used at that time.

Painting, enamel, glass, and dyeing techniques reached an advanced state of development in Egypt and Babylon. A synthetic lapis lazuli (a silicate of copper and calcium) is still known as Egyptian blue. Antimony sulfide and galena (lead sulfide) were commonly used as black pigments, cinnabar as a red pigment, and ground cobalt glass and cobalt aluminum oxide as blue pigments. According to PLUTARCH, the Greeks and Romans did not regard the art of dyeing very highly, and made very little contribution to the development of new pigments. PLINY (23 – 79 A.D.) describes the pigments orpigment, realgar, massicot, red lead, white lead, verdigris, and pigments laked with alum, as well as the pigments already listed above. Certain types of chalk and clay were used as white pigments.

From the age of the migration of the peoples (fourth to sixth century A.D.) to the end of the late Middle Ages, there were no notable additions to the range of coloring materials. The reinvented pigment Naples yellow and certain dyestuffs for textiles from the orient were the only innovations. New developments in the field of pigments first occurred during the early Renaissance. Carmine was introduced from Mexico by the Spanish. Smalt, safflore, and cobalt-containing blue glasses were developed in Europe (⟶ Cobalt and Cobalt Compounds – Introduction).

The pigment industry started in the 18th century with products such as Berlin blue (1704), cobalt blue (1777), Scheele's green, and chrome yellow (1778).

In the 19th century, ultramarine, Guignet's green, cobalt pigments, iron oxide pigments, and cadmium pigments were developed in quick succession.

In the 20th century, pigments increasingly became a subject of scientific investigation. In the past few decades, the synthetic colored pigments cadmium red, manganese blue, molybdenum red, and mixed oxides with bismuth came onto the market. Titanium dioxide with anatase or rutile structures, and acicular zinc oxide were introduced as new synthetic white pigments and extenders, respectively. Luster pigments (metal effect, nacreous, and interference pigments) have assumed increasing importance.

Economic Aspects. World production of pigments in 2005 was ca. 7.4×10^6 t. Inorganic pigments accounted for ca. 97 % of this.

About one-third of this total is supplied by the United States, one-third by the European Community, and one-third by all the remaining countries. The German owned pigment industry supplied more than 40 % of the world consumption of inorganic colored pigments, including about 50 % of the iron oxides. Estimated world consumption of inorganic pigments in 2005 can be broken down as follows:

Titanium dioxide	68 %
Synthetic iron oxides	10 %
Carbon black pigments	12 %
Lithopone	4 %
Chromium oxide	1 %
Luster pigments	< 1 %
Mixed metal oxide pigments	< 0.5 %
Ultramarine	< 0.5 %

Pigment production is still a growth industry, but in the future the growth rate will decrease. The names of manufacturing companies are given in the corresponding.

Uses. The most important areas of use of pigments are paints, varnishes, plastics, artists' colors, printing inks for paper and textiles, leather decoration, building materials (cement, renderings, concrete bricks and tiles — mostly based on iron oxide and chromium oxide pigments), leather imitates, floor coverings, rubber, paper, cosmetics, ceramic glazes, and enamels.

The paint industry uses high-quality pigments almost exclusively. An optimal, uniform particle size is important because it influences gloss, hiding power, tinting strength, and lightening power. Paint films must not be too thick, therefore pigments with good tinting strength and hiding power combined with optimum dispersing properties are needed.

White pigments are used for white coloring and covering, but also for reducing (lightening) colored and black pigments. They must have a minimal intrinsic color tone.

When choosing a pigment for a particular application, several points normally have to be considered. The coloring properties (e.g., color, tinting strength or lightening power, hiding power, see Section Color Properties) are important in determining application efficiency and hence economics. The following properties are also important:

1. *General chemical and physical properties:* chemical composition, moisture and salt content, content of water-soluble and acid-soluble matter, particle size, density, and hardness (see Section General Chemical and Physical Properties)
2. *Stability properties:* resistance toward light, weather, heat, and chemicals, anticorrosive properties, retention of gloss (see Section Stability Towards Light, Weather, Heat, and Chemicals)
3. *Behavior in binders:* interaction with the binder properties, dispersibility, special properties in certain binders, compatibility, and solidifying effect (see Section Behavior of Pigments in Binders)

Important pigment properties and the methods for determining them are described later.

Classification. Inorganic pigments can be classified from various points of view. The classification given in Table 2 (for standards see Table 1, "Coloring materials, terms") follows a system recommended by ISO and DIN; it is based on coloristic and chemical considerations. As in many classification schemes, there are areas of overlap between groups so that sharp boundaries are often impossible. In this article white pigments are described in Chapter White Pigments, colored pigments in Chapter Colored Pigments, and specialty pigments in Chapter Specialty Pigments. For black pigments, see ⟶ Carbon – Carbon Black.

Table 2. Classification of inorganic pigments

Term	Definition
White pigments	the optical effect is caused by nonselective light scattering (examples: titanium dioxide and zinc sulfide pigments, lithopone, zinc white)
Colored pigments	the optical effect is caused by selective light absorption and also to a large extent by selective light scattering (examples: iron oxide red and yellow, cadmium pigments, ultramarine pigments, chrome yellow, cobalt blue)
Black pigments	the optical effect is caused by nonselective light absorption (examples: carbon black pigment, iron oxide black)
Luster pigments	the optical effect is caused by regular reflection or interference
Metal effect pigments	regular reflection takes place on mainly flat and parallel metallic pigment particles (example: aluminum flakes)
Nacreous pigments	regular reflection takes place on highly refractive parallel pigment platelets (example: titanium dioxide on mica)
Interference pigments	the optical effect of colored luster pigments is caused wholly or mainly by the phenomenon of interference (example: iron oxide on mica)
Luminescent pigments	the optical effect is caused by the capacity to absorb radiation and to emit it as light of a longer wavelength
Fluorescent pigments	the light of longer wavelength is emitted after excitation without a delay (example: silver-doped zinc sulfide)
Phosphorescent pigments	the light of longer wavelength is emitted within several hours after excitation (example: copper-doped zinc sulfide)

1.2. General Chemical and Physical Properties

1.2.1. *Fundamental Aspects [2]*

Chemical Composition. With few exceptions, inorganic pigments are oxides, sulfides, oxide hydroxides, silicates, sulfates, or carbonates (see Tables 3 and 4), and normally consist of single-component particles (e.g., red iron oxide, α-Fe_2O_3) with well-defined crystal structures. However, mixed and substrate pigments consist of nonuniform or multicomponent particles.

Table 3. Classification of white and black pigments

Chemical class	White pigments	Black pigments
Oxides	titanium dioxide	iron oxide black
	zinc white, zinc oxide	iron – manganese black
		spinel black
Sulfides	zinc sulfide	
	lithopone	
Carbon and carbonates	white lead	carbon black

Table 4. Classification of inorganic colored pigments

Chemical class	Green	Blue-green	Blue	Violet	Red	Orange	Yellow	Brown
Oxides and oxide – hydroxides								
Iron oxide pigments					iron oxide red	iron oxide orange	iron oxide yellow	iron oxide brown
Chromium	chromium	chromium						

oxide pigments	oxide	oxide hydrate green					
Mixed metal oxide pigments		cobaltgreen and blue			chromium rutile orange	nickel rutile yellow, chromium rutile yellow	zinc iron spinel, Mn – Fe brown
Sulfide and sulfoselenide pigments				cadmium sulfoselenide		cadmium sulfide, (Cd, Zn)S	
Chromate pigments	chrome green			molybdate red	chrome orange	chrome yellow, zinc yellow	
Ultramarine pigments		ultramarine green, blue, violet, and red					
Iron blue pigments		iron blue					
Others		manganese blue	cobalt manganese violet			Naples yellow, bismuth vanadate	

Mixed pigments are pigments that have been mixed or ground with pigments or extenders in the dry state (e.g., chrome green pigments are mixtures of chrome yellow and iron blue). If the components differ in particle size and shape, density, reactivity, or surface tension, they may segregate during use.

In the case of *substrate pigments*, at least one additional component (pigment or extender) is deposited onto a substrate (pigment or extender), preferably by a wet method. Weak, medium, or strong attractive forces develop between these pigment components during drying or calcining. These forces prevent segregation of the components during use.

Special substrate pigments include the aftertreated pigments and the core pigments. To produce *aftertreated pigments* the inorganic pigment particles are covered with a thin film of inorganic or organic substances to suppress undesirable properties (e.g., catalytic or photochemical reactivity) or to improve the dispersibility of the pigments and the hydrophilic or hydrophobic character of their surfaces. The particles can be coated by precipitation (e.g., aftertreated TiO_2 pigments, see Section Aftertreatment), by adsorption of suitable substances from solutions (usually aqueous), or by steam hydrolysis.

To produce *core pigments*, a pigment substance is deposited on an extender by precipitation or by wet mixing of the components. In the case of anticorrosive pigments (see Section Principles), whose protective effect is located on their surfaces, the use of core pigments can bring about a significant saving of expensive material. Extender particles are also treated by fixing water-insoluble organic dyes on their surfaces via lake formation.

Analysis. The industrial synthesis of inorganic pigments is strictly controlled by qualitative and quantitative chemical analysis in modern, well-equipped physico-chemical test laboratories. Quantitative chemical and X-ray analysis is carried out on raw materials, intermediates, and substances used for aftertreatment, but most importantly on the final products, byproducts, and waste products (wastewater and exhaust gas). This serves not only to fulfil quality requirements but also the demands of environmental protection. Quality control, carried out in specially equipped laboratories and supported by computers, includes testing of physical and technical application properties [3], [4]. Information on quality requirements for inorganic pigments is widely available in international (ISO), European (EN), and national standards (e.g., AFNOR, ASTM, BSI, DIN) [5], [6]. Standard analytical methods and conditions of delivery for the most important inorganic pigments are given in Table 1. Further information is given in later sections.

Crystallography and Spectra. The following are the most common crystal classes:

1. *Cubic*: zinc blende lattice (e.g., precipitated CdS), spinel lattice (e.g., Fe_3O_4, $CoAl_2O_4$)
2. *Tetragonal*: rutile lattice (e.g., TiO_2, SnO_2)
3. *Rhombic*: goethite lattice (e.g., α-FeOOH)
4. *Hexagonal*: corundum lattice (e.g., α-Fe_2O_3, α-Cr_2O_3)
5. *Monoclinic*: monazite lattice (e.g., $PbCrO_4$)

In ideal solid ionic compounds, the absorption spectrum is composed of the spectra of the individual ions, as is the case in ionic solutions. For metal ions with filled *s, p,* or *d* orbitals, the first excited energy level is so high that only ultraviolet light can be absorbed. Thus, when the ligands are oxygen or fluorine, white inorganic compounds result. The absorption spectra of the chalcogenides of transition elements with incompletely filled *d* and *f* orbitals are mainly determined by the charge-transfer spectrum of the chalcogenide ion which has a noble gas structure. For the transition metals, lanthanides, and actinides, the energy difference between the ground state and the first excited state is so small that wavelength-dependent excitations take place on absorption of visible light, leading to colored compounds [7].

X-Ray investigation of inorganic pigments yields information on the structure, fine structure, state of stress, and lattice defects of the smallest coherent regions that are capable of existence (i.e., crystallites) and on their size. This information cannot be obtained in any other way. Crystallite size need not be identical with particle size as measured by the electron microscope, and can, for example, be closely related to the magnetic properties of the pigment.

Particle Size. The important physical data for inorganic pigments comprise not only optical constants, but also geometric data: mean particle size, particle size distribution, and particle shape [8]. The standards used for the terms that are used in this section are listed in Table 1 ("Particle size analysis").

The concept of *particles and particle shape* corresponds to that used in the recommended and internationally accepted classification of pigment particles given in [9] (see Fig. 1 and Table 5).

Table 5. Definitions of particles and associated terms (see also Fig. 1)

Term	Definition
Particle	individual unit of a pigment that can have any shape or structure
Primary or individual particles	particles recognizable as such by appropriate physical methods (e.g., by optical or electron microscopy)
Aggregate	assembly of primary particles that have grown together and are aligned side by side; the total surface area is less than the sum of the surface areas of the primary particles
Agglomerate	assembly of primary particles (e.g., joined together at the corners and edges), and/or aggregates whose total surface area does not differ appreciably from the sum of the individual surface areas
Flocculate	agglomerate present in a suspension (e.g., in pigment–binder systems), which can be disintegrated by low shear forces

Figure 1. Primary particles, agglomerates, and aggregates

The term *particle size* must be used with care, as is borne out by the large number of different "particle diameters" and other possible terms used to denote size (see Table 6). In granulometry, so-called *shape factors* are often used to convert equivalent diameters to "true" diameters. However, the determination and use of shape factors is problematic.

Table 6. Particle size, particle size distribution, and characteristic quantities

Term	Definition
Particle size	geometrical value characterizing the spatial state of a particle
Particle diameter D_{eff}	diameter of a spherical particle or characteristic dimension of a regularly shaped particle
Equivalent diameter D	diameter of a particle that is considered as a sphere
Particle surface area S_T	surface area of a particle: a distinction is made between the internal and external surface areas
Particle volume V_T	volume of a particle: a distinction is made between effective volume (excluding cavities) and apparent volume (including cavities)
Particle mass m_T	mass of a particle
Particle density Q_T	density of a particle
Particle size distribution	statistical representation of the particle size of a particulate material
Distribution density	gives the relative amount of a particulate material in relation to a given particle size diameter. Density distribution functions must always be normalized
Cumulative distribution	normalized sum of particles that have a diameter less than a given particle size parameter
Fractions and class	a fraction is a group of particles that lies between two set values of the chosen particle size parameter that limits the class
Mean value and other similar parameters	the mean values of particle size parameters can be expressed in many ways, some values are used frequently in practice
Distribution spread	parameter for characterizing the nonuniformity of the particle size

In practice, empirically determined *particle size distributions* are represented by:

1. Tabulated results
2. Graphical representation in the form of a histogram (bar chart) or as a continuous curve
3. Approximation in the form of analytical functions

For standards see Table 1 "Particle size, representation".

Special distribution functions are specified in some standards (e.g., power distribution, logarithmic normal distribution, and RRSB distribution). The representation of particle size distributions and methods for their determination are described elsewhere (⟶ Particle Size Analysis and Characterization of a Classification Process). Methods of determination for pigments are rated in Section Methods of Determination.

The important parameters relating to particle size distribution are the *mean particle size* and the *spread of the distribution.* The way of expressing the mean particle size depends on the test method used or on which mean value best reflects the pigment property of interest. Depending on the spread of parameter, the various mean values for a given particulate material can differ considerably. The mean particle sizes of inorganic pigments lie in the range 0.01 – 10 µm, and are usually between 0.1 and 1 µm.

The *specific surface area* also represents a mean of the pigment particle size distribution. It can be used to calculate the mean diameter of the surface distribution. Care must be taken that the effect of the "internal surface area" is taken into account. If the product has an internal surface area which cannot be neglected in comparison to the external surface area, then the measured specific surface area no longer gives a true measure of the mean diameter. This applies, for instance, to aftertreated pigments because the treatment material is often very porous.

For anisometric particles (e.g., needle- or platelet-shaped particles) mathematical statistics may likewise be applied [10]. The two-dimensional logarithmic normal distribution of the length L and breadth B of the particles also allows the representation and calculation of the characteristic parameters and mean values. The eccentricity of the calculated standard deviation ellipse (Fig. 2) is a measure of the correlation between the length and breadth of the particle. By using more than two particle fineness parameters, this principle can be further extended in a similar manner.

Figure 2. Standard deviation ellipses of a logarithmic normal distribution (yellow iron oxide pigment)

$\bar{L}_z$, $\bar{B}_z$ = median of L, B

The effect of particle size on optical properties of pigments is described in Section Color Properties.

1.2.2. *Methods of Determination*

General Methods. *Sampling* with a suitable device (beaker, sampling scoop) is applicable for solid materials, especially pigments, fillers, and resins in powder, granular, or lump form. For standards, see Table 1 ("Sampling").

Standard climates are constant artificial climatic conditions with a defined temperature and humidity and limited ranges of air pressure and flow velocity. They can be set up in "clima" cabinets, closets, or rooms. The standard climate 23/50 (23 °C and 50 % relative humidity) is recommended. For standards, see Table 1 ("Climates").

Evaluation Methods. In testing paint materials, paints, and other coating materials, the properties or variations in properties often cannot be described quantitatively but must be assessed subjectively. A uniform system of evaluation has been established in the form of a numerical scale to facilitate the assessment of results and mutual understanding. This system should only be used if a result cannot be obtained as a directly measured value. For standards, see Table 1 ("Test evaluation").

Matter Volatile and Loss on Ignition. The content of *matter volatile* in a pigment is determined by drying a sample in an oven at 105 ± 2 °C. This normally gives a measure of the moisture content. For standards, see Table 1 ("Matter volatile").

Loss on ignition is determined by various means depending on the pigment. The principle is the same in all the methods: a weighed sample is heated to a predetermined temperature, cooled in a desiccator, and reweighed. Special standard procedures are specified for iron oxide pigments and carbon black. For standards, see Table 1 ("Iron oxide pigments: Specifications" and "Carbon black pigments: Specifications").

Aqueous Extracts. The content of *matter soluble in water* in pigments is determined by hot or cold extraction of the pigments under prescribed testing conditions. For

standards, see Table 1 ("Matter soluble in water"). The decision whether to use hot or cold extraction depends on the properties of the pigment and should be agreed between the interested parties unless otherwise prescribed.

The *pH value* of a pigment denotes the pH of an aqueous suspension of the pigment prepared in a prescribed manner. For standards, see Table 1 ("pH value"). Apparatus: pH meter.

The *electrical conductivity* (or resistivity) of an aqueous pigment extract is determined from the electrical conductance (or resistance). For standards, see Table 1 ("Resistivity"). Apparatus: centrifuge with glass containers, resistance measurement bridge, electrolytic cell.

The *acidity* or *alkalinity* is measured as the quantity of cubic centimeters of 0.1 N alkali (NaOH or KOH) or acid solution that are required to neutralize an aqueous extract of 100 g pigment under prescribed conditions. Unless otherwise agreed, the pigment is extracted with hot water. If cold water is used, this must be specifically stated. For standards, see Table 1 ("Acidity/alkalinity"). Test reagents: 0.5 N HCl or H_2SO_4, 0.5 N NaOH or KOH, indicators (by agreement).

Water-Soluble Sulfates, Chlorides and Nitrates. The procedures are applicable to pigments and extenders. The choice of hot or cold extraction depends on the properties of the pigment and should be agreed. The anions are determined by the usual analytical methods. For standards, see Table 1 ("Sulfates", "Chlorides", and "Nitrates"). Apparatus: Nessler tubes or spectrophotometer, equipment for pH measurement.

Water-Soluble Chromium(VI). Chromium(VI) is determined photometrically in an aqueous extract obtained by hot or cold extraction using the color produced with diphenylcarbazide, or directly as chromate. For standards, see Table 1 ("Matter soluble in water"). Apparatus: equipment for shaking conical flasks, photometer with glass cells, pH meter.

Matter Soluble in HCl. The pigment is extracted with 0.1 mol/L hydrochloric acid under prescribed conditions to determine the content of As, Ba, Cd, Co, Cr, Cr(VI), Cu, Hg, Mn, Ni, Pb, Sb, Se, and Zn. For standards, see Table 1 ("Matter soluble in HCl"). Apparatus: shaker for conical flasks.

Particle Size Distribution. Methods for determining the particle size of pigments should provide not only the mean particle size but also the complete particle size distribution. Thus, it is preferable to use methods that give not only the parameters of a particular distribution function, but also allow direct measurement of the true particle size distribution. Methods of determination are given in ⟶ Particle Size Analysis and Characterization of a Classification Process. Closely specified standard methods of determination exist for particle sizes >1 µm. Several methods have been developed for the particle size region of particular relevance to pigments (<1 µm). The following methods are used:

1. Counting particles on an electron micrograph (⟶ Particle Size Analysis and Characterization of a Classification Process – Image Analysis)
2. Sedimentation analysis (⟶ Particle Size Analysis and Characterization of a Classification Process – Sedimentation Analysis)
3. Optical methods (⟶ Particle Size Analysis and Characterization of a Classification Process – Measurement by Light Scattering or Absorption).
4. Other methods that are based on physical volume effects (e.g., the Coulter counter, based on electrical conductivity, ⟶ Particle Size Analysis and Characterization of a Classification Process – Electrical Sensing Zone Method)

Particle counting of electron micrographs is performed on a computer screen with an automatic counting apparatus. In order to minimize errors, at least 2500 (but preferably 10 000) particles must be counted.

For pigments, counting is the most suitable method for several reasons. The counting operation is carried out in the binder medium of interest, whereas with sedimentation analysis or the Coulter counter the medium cannot be freely chosen. Furthermore, counting can be carried out under the dispersion conditions used for examination (in contrast to methods in which a specified binder medium must be used that can lead to a different state of dispersion). Problems associated with concentration are much less frequent than in other methods, which sometimes require extremely dilute suspensions (especially optical analysis and the Coulter counter). Another problem with optical analysis is that calibration is often difficult because the absolute scattering and absorption functions of real particles are not well known, and because isodisperse particulate matter is usually not available to draw up a calibration curve. The most important advantages of the counting technique based on electron micrographs lie in the direct observation of the particle shapes and in the ability to distinguish between primary particles, agglomerates, and aggregates.

Sedimentation analysis uses either the earth's gravitational field or a centrifugal field. Owing to the small size of pigment particles (<1 µm), the time taken for sedimentation in the gravitational field is considerable. This has led to developments in centrifugal sedimentation techniques, both as regards apparatus (centrifuges, disk-shaped rotors) and methods (two-layer technique). For standards, see Table 1 ("Particle size analysis: Sedimentation method"). The rate of fall of a single particle in a liquid in a gravitational or centrifugal field gives a measure of the particle size. Methods of measurement differ in the approach used to determine the different particle size fractions:

1. *Suspension Methods.* Analysis starts with a suspension in which a representative sample of the dispersed solid is homogeneously distributed over the whole of the sedimentation depth.
2. *Two-Layer Method.* A suspension is spread in a thin layer on the surface of a clear, solids-free liquid. The particles then fall through the liquid in order of decreasing sedimentation velocity and reach the measuring plane in succession.

In *optical methods*, extremely dilute aqueous or air-fluidized pigment suspensions are almost exclusively used. Instruments for the 0.1 – 10 µm particle size region mostly use Fraunhofer diffraction with additional correction for Mie scattering on small particles. Optical methods allow quick and reproducible measurements. Unfortunately, information is not usually available concerning the optical constants of the sample; this causes drawbacks as regards absolute particle size data.

Sieve Analysis. The sieving residue can be determined by two methods:

1. *Wet Sieving by Hand*. In the utilization of pigments, it is important to know the content of pigment particles that are appreciably larger than the mean particle size. This material can consist of coarse impurities, pigment aggregates (agglomerates), or large primary particles. The dried pigment is washed with water through a sieve of the appropriate mesh size, and the retained material is determined gravimetrically after drying. For standards, see Table 1 ("Residue on sieve: By water").
2. *Wet Sieving by a Mechanical Flushing Procedure.* The sieve residue is the portion of coarse particles that cannot be washed through a specified test sieve with water. The result depends on the mesh size of the sieve. For standards, see Table 1 ("Residue on sieve: Mechanical method"). Apparatus: Mocker's apparatus.

The *specific surface* is usually understood to mean the area per unit mass of the solid material, but it is sometimes useful to relate the surface area to the volume of the solid (see Section Fundamental Aspects). The specific surface area can only be determined indirectly owing to the small size of the pigment particles:

1. *Gas Adsorption by the Brunauer, Emmett, and Teller (BET) Method.* The specific surface area of porous or finely divided solids is measured. The method is limited to solids that do not react with the gas used (e.g., while the gas is adsorbed), and nonmicroporous materials. For standards, see Table 1 ("Specific Surface, BET Method" and "N_2 Adsorption").
2. *Carman's Gas Permeability Method*. A gas or a wetting liquid is made to flow through the porous material in a tube by applying vacuum or pressure. The pressure drop or flow rate is measured. For pigments, a modified procedure is used in which mainly nonlaminar flow takes place [11]. For standards, see Table 1 ("Specific surface: Permeability techniques").

Pigment Density. *Density* is determined by pyknometry at a standard temperature of 25 °C. For standards, see Table 1 ("Density"). Apparatus: pyknometer, vacuum pump or centrifuge.

The *apparent density* of a powdered or granulated material after tamping is the mass (g) of 1 cm^3 of the material after tamping in a tamping volumeter under prescribed conditions. The *tamped volume* is the volume (cm^3) of 1 g of the material. Tamped volume and apparent density after tamping depend mainly on the true density, shape, and size of the particles. A knowledge of these parameters allows decisions to be made regarding dimensions of packing materials and product uniformity. For standards, see Table 1 ("Tamped volume"). Apparatus: tamping volumeter.

Hardness and Abrasiveness. The abrasiveness of a pigment is not identical to its intrinsic hardness, i.e., the hardness of its primary particles. In practice the Mohs hardness is not therefore a useful indication of the abrasiveness of a pigment. Abrasion rather depends on pigment particle size and shape and is usually caused by the sharp edges of the particles. A standard test procedure for determining abrasiveness does not exist. A method based on the abrasion of steel balls by the pigment is described in [12].

1.3. Color Properties

1.3.1. *Fundamental Aspects [13-16]*

When a photon enters a pigmented film, one of three events may occur:

1. It may be absorbed by a pigment particle
2. It may be scattered by a pigment particle
3. It may simply pass through the film (the binder being assumed to be nonabsorbent)

The important physical – optical properties of pigments are therefore their light-absorption and light-scattering properties. If absorption is very small compared with scattering, the pigment is a white pigment. If absorption is much higher than scattering over the entire visible region, the pigment is a black pigment. In a colored pigment, absorption (and usually scattering) are selective (i.e., depend on wavelength).

Pigments and coatings may be unambiguously characterized by their spectral reflectance curves $\varrho(\lambda)$ or spectral reflectance factor curves $R(\lambda)$ (Fig. 3). The reflectance spectrum $\varrho(\lambda)$ or $R(\lambda)$ and hence the color properties can be almost completely derived from physical quantities [15] (Fig. 4):

1. *Colorimetry* relates the perceived color quality to the color stimulus, which in turn is based on the reflectance spectrum $\varrho(\lambda)$.
2. The *Kubelka – Munk theory* relates $\varrho(\lambda)$ to scattering, absorption, and film thickness (scattering coefficient *S*, absorption coefficient *K*, film thickness *h*).
3. The *theory of multiple scattering* (scattering interaction) relates the scattering coefficient *S* to the pigment volume concentration σ and to the scattering diameter Q_S of the individual particle. The absorption coefficient *K* is directly proportional to the absorption diameter Q_A and the concentration σ.
4. In *Mie's theory*, the scattering diameter Q_S and the absorption diameter Q_A are related to the particle size *D*, the wavelength λ, and the optical constants of the material (refractive index n and absorption index κ).

Figure 3. Spectral reflectance curves of some inorganic pigments in paints

a) Manganese blue; b) CdS; c) α-FeOOH; d) α-Cr_2O_3; e) α-Fe_2O_3

Figure 4. The relationships between the optical properties of pigments and their theoretical basis

Colorimetry [17-19]. The principles of colorimetry (⟶ Dyes, General Survey – Color Measurement and Colorant Formulation) are based on the fact that all color stimuli can be simulated by additively mixing only three selected color stimuli (trichromatic principle). A color stimulus can, however, also be produced by mixing the spectral colors. Thus, it has a spectral distribution, which in the case of nonluminous, perceived colors is called the spectral reflectance $\varrho(\lambda)$. After defining three reference stimuli, the trichromatic principle allows a three-dimensional color space to be built up in which the color coordinates (tristimulus values) can be interpreted as components of a vector (CIE system; for standards, see Table 1, "Colorimetry"; CIE = Commission Internationale de l'Éclairage). The three CIE tristimulus values depend on the spectral reflectance $\varrho(\lambda)$ and the spectrum of the iluminant $S(\lambda)$ as follows:

$$X = \int_{400}^{700} \bar{x}(\lambda)\varrho(\lambda)S(\lambda)\mathrm{d}\lambda$$

$$Y = \int_{400}^{700} \bar{y}(\lambda)\varrho(\lambda)S(\lambda)\mathrm{d}\lambda$$

$$Z = \int_{400}^{700} \bar{z}(\lambda)\varrho(\lambda)S(\lambda)\mathrm{d}\lambda$$

where $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$ are the CIE tristimulus values of the spectral colors and are called the CIE spectral tristimulus values (color matching function). The CIE chromaticity coordinates (*x, y*, and *z*) are given by

$$x = \frac{X}{X+Y+Z};$$

$$y = \frac{Y}{X+Y+Z};$$

$$z = 1 - x - y$$

They are represented as coordinates in a color plane. The chromaticity coordinates *x* and *y* are used to specify the saturation and hue of any color in the CIE chromaticity diagram (see ⟶ Dyes, General Survey). The CIE spectral tristimulus value $\bar{y}(\lambda)$ corresponds to the lightness sensitivity curve of the human eye. Therefore, a third color variable is specified in addition to *x* and *y*, namely the CIE tristimulus value *Y*, which is a measure of lightness.

This system allows exact measurement of color with worldwide agreement. For pigment testing, however, this is not sufficient because small color differences usually have to be determined and evaluated (e.g., between test and reference pigment). Using the CIE system, it is certainly possible to say which spectral distributions are visually identical, but this is not suitable for determining color differences. To establish color differences an "absolute color space" must be used. Here, colors are arranged three-dimensionally such that the distance between two colors in any direction in space corresponds to the perceived difference. Such a type of color space can be based on the color qualities lightness, hue, and saturation. Several such systems exist. The most widespread color system is probably the Munsell system, which is available in the form of an atlas.

For the quantitative determination of color differences, the transformation relationships between the CIE system (which has to be used for color measurement) and the physiologically equidistant color system must be established. Color differences can then be calculated in the latter system. A large number of color difference systems have been developed, mainly as a need of industrial color testing.

The Adams – Nickerson (AN) system, well-known for many decades and derived from the Munsell system, was recommended for pigment testing by DIN (German Standards Institute) and later worldwide by the CIE ("CIELAB"; for standards, see Table 1, "Color differences"). The three coordinates are denoted by *a** (red – green axis), *b** (the yellow – blue axis), and *L** (the lightness axis). To calculate the CIELAB coordinates, *X, Y*, and *Z* are first converted into the functions *X**, *Y**, and *Z** by using a relationship that approximately takes account of the physiologically equidistant lightness steps:

$$X^* = \sqrt[3]{X/X_n};$$

$$Y^* = \sqrt[3]{Y/Y_n};$$

$$Z^* = \sqrt[3]{Z/Z_n}$$

where X_n, Y_n, and Z_n are the CIE tristimulus values of the illuminant, especially a standard illuminant. For radicands < 0.008856, these equations become:

$$X^* = (7.787X/X_n) + 0.138$$

$$Y^* = (7.787Y/Y_n) + 0.138$$

$$Z^* = (7.787Z/Z_n) + 0.138$$

Values of *a**, *b**, and *L** are obtained from the values of *X **, *Y **, and *Z**:

$$a^* = 500\left(X^* - Y^*\right)$$

$$b^* = 200\left(Y^* - Z^*\right)$$

$$L^* = 116Y^* - 16$$

The components of the color difference are obtained as differences between the test sample (T) and the reference pigment (R):

$$\Delta a^* = a^*_T - a^*_R;\ \Delta b^* = b^*_T - b^*_R;\ \Delta L^* = L^*_T - L^*_R$$

The color difference is finally calculated as the geometrical distance between the two positions in the CIELAB color space:

$$\Delta E^*_{ab} = \sqrt{\Delta a^{*2} + \Delta b^{*2} + \Delta L^{*2}}$$

An important advantage of the CIELAB system is that the resulting color difference can be split up into component contributions, namely lightness, saturation, and hue, corresponding to the arrangement of the color space:

Lightness difference

$$\Delta L^* = L^*_{\mathrm{T}} - L^*_{\mathrm{R}}$$

Chroma difference (saturation difference)

$$\Delta C^*_{ab} = \sqrt{a^{*2}_{\mathrm{T}} + b^{*2}_{\mathrm{T}}} - \sqrt{a^{*2}_{\mathrm{R}} + b^{*2}_{\mathrm{R}}}$$

Hue difference

$$\Delta H^*_{ab} = \sqrt{\Delta E^{*2}_{ab} - \Delta L^{*2} - \Delta C^{*2}_{ab}}$$

The CIE has proposed a new color difference formula based on CIELAB. The new “CIE94” formula is [20] (for standards see Table 1, “Color Differences, CIE94”):

$$\Delta E^*_{94} = \sqrt{\left(\frac{\Delta C^*_{ab}}{k_C S_C}\right)^2 + \left(\frac{\Delta H^*_{ab}}{k_H S_H}\right)^2 + \left(\frac{\Delta L^*}{k_L S_L}\right)^2}$$

where $S_L = 1$, $S_C = 1 + 0.045\, C^*_{ab,\mathrm{R}}$, $S_H = 1 + 0.015\, C^*_{ab,\mathrm{R}}$, ($C^*_{ab,\mathrm{R}}$ is the chroma of the reference).

Here the k_i are the parameters of externally imposed conditions, such as conditions specific to a certain application or conditions differing from the standard conditions. The standard conditions are as follows: Illuminant D65, ca. 1000 1x, surroundings gray $L^* = 50$, ca. 100 cd/m^2, sample size over 4°, sample pair without gap between, homogeneous texture, $0 < \Delta E^*_{94} < 5$. Under these conditions, $k_L = k_C = k_H = 1$.

If neither of the two samples has been defined as the reference, C^*_{ab} should be taken equal to the geometric mean of $C^*_{ab,1}$ and $C^*_{ab,2}$.

For coating color testing, the weaknesses of the CIE system can be compensated by a suitable choice of parametric factors, for example $k_H/k_C = 1$ and $3 \le k_H/k_L \le 4$.

A number of color laboratories have recently had good experience with another color-difference system, the CMC system. (CMC: *C*olour *M*easurement *C*ommittee of the Society of Dyers and Colourists in the British Standards Institution (BSI)). For standards see “Color differences: CMC” in Table 1 and British Standard BS 6923.

The CIE has established a new color difference system: CIE DE 2000. The formulae, as taken from Technical Report CIE 142-2001, are given below:

$$\Delta E^2_{00} = \left(\frac{\Delta L'}{k_L S_L}\right)^2 + \left(\frac{\Delta C'}{k_C S_C}\right)^2 + \left(\frac{\Delta H'}{k_H S_H}\right)^2 + R_T \frac{\Delta C' \Delta H'}{k_C S_C k_H S_H}.$$

In the formula R_T is the rotation function, which is defined as

$$R_T = -\sin(2\Delta\theta) R_C \quad \text{with } \Delta\theta = 30 e^{-\left(\frac{R-275}{25}\right)^2} \quad \text{and}$$
$$R_c = 2\sqrt{\frac{\overline{C}'^7}{\overline{C}'^7 + 25^7}} \, and \, \overline{C} = \frac{1}{2}(C'_1 + C'_2).$$

The symbols used are defined as

$$L = L^*;\ a' = a^*(1+G);\ b' = b^*,$$
$$G = \frac{1}{2}\left(1 - \sqrt{\frac{C^{*7}_{ab}}{\overline{C}^7_{ab}{}^* + 25^7}}\right)$$
$$\text{with } \overline{C}^*_{ab} = \frac{1}{2}(C^*_{ab,1} + C^*_{ab,2})$$
$$C' = \sqrt{a'^2 + b'^2},$$
$$h' = \mathrm{Arctan}\frac{b'}{a'}$$

The color differences are formed according to the conventional method as the differences between the sample and the reference. The weighting functions are indicated below

$$S_L = 1 + \frac{q(\overline{L}' - 50)^2}{\sqrt{20 + (\overline{L}' - 50)^2}} \quad \text{with } q$$
$$= 0.015 \, and \, \overline{L}' = \frac{1}{2}(L'_1 + L'_2)$$
$$S_c = 1 + p\overline{C}' \text{ with } p = 0.045,$$
$$S_H = 1 + q\overline{C}' T \text{ with}$$
$$T = 1 - 0.17 \cos(\overline{h}' - 30) + 0.24 \cos(2\overline{h}')$$
$$+0.32 \cos(3\overline{h}') 0.2 \cos(4\overline{h}' - 63).$$
$$\text{and } \overline{h}' = \frac{1}{2}(h'_1 + h'_2).$$

The term containing R_T leads to a certain problem and is in contradiction to the fundamental equation for Euclidean color differences from STILES [21]:

$$ds^2 = dU_1^2 + dU_2^2 + dU_3^2 (\text{or } ds^2 = dr^2 + r^2 d\rho^2 + dU_3^2)$$

Further, as in practice, it is often necessary to break down the total color difference into its individual components ΔC, ΔH, ΔL, in order to assess its quality. In case of the first equation the last term on the right-hand side will remain, because it cannot be associated to either *C* or *H*. Therefore, the rotation must be incorporated directly into the components ΔC and ΔH.

Kubelka – Munk Theory. The Kubelka – Munk theory [22], [23] (see also ⟶ Dyes, General Survey – Colorant Formulation) is based on the fact that the optical properties of a film which absorbs and scatters light may be described by two constants: the absorption coefficient *K* and the scattering coefficient *S*. In a simplification, the flux of the diffuse incident light is represented by a single beam L^+, and the flux of the light scattered in the opposite direction by a beam L^-. Each beam is attenuated by absorption and scattering losses, but is reinforced by the scattering losses of the respectively opposite beam. The absorption and scattering losses are determined quantitatively by the two coefficients *K* and *S*. A simple system of two linked differential equations can be written. These can be integrated for the valid boundary conditions at the incident light side, and at the opposite side. Solutions for the transmittance τ and the reflectance ϱ are obtained from these integrals as a function of the absorption coefficient *K*, the scattering coefficient *S*, the film thickness *h*, and in special cases of the reflectance ϱ_o of a given substrate.

The most important and widely used quantity derived from the Kubelka – Munk theory is the reflectance of an opaque (infinitely thick) film that is described by a very simple equation:

$$K/S = (1 - \varrho_\infty)^2 / (2\varrho_\infty)$$

From this expression (Kubelka – Munk function) it follows that, within the range of validity of the theory, ϱ_∞ depends only on the ratio of the absorption coefficient to the scattering coefficient, and not on their individual values. The equation has been most useful where reflectance measurements are used to obtain information about

absorption and scattering (e.g., in textile dyeing, thin layer chromatography, and IR spectroscopy).

This theory is especially useful for computer color matching of pigmented systems [24-26]: absorption and scattering coefficients are combined additively using the specific coefficients of the components multiplied by their concentrations.

Multiple Scattering. The absorption coefficient *K* obeys Beer's law even at high pigment volume concentrations σ, and is therefore proportional to σ (Fig. 5). The relationship between the scattering coefficient *S* and the concentration gives rise to problems, however. The distance between the pigment particles decreases with increasing concentration; consequently there is interaction and hindrance between the light scattered by individual particles, and their scattering power usually falls. The scattering coefficient *S* is therefore linearly related to concentration only at low concentrations (the Beer's law region), at higher concentrations it remains below the linear value (Fig. 6). The concentration dependence of the scattering coefficient can be quantitatively represented by using empirical formulae [27], e.g., there is a linear relationship between S/σ and $\sqrt[3]{\sigma}$.

Figure 5. Absorption coefficient *K* for diffuse illumination as a function of the pigment volume concentration for three red iron oxide pigments

Figure 6. Scattering coefficients as a function of pigment volume concentration

Mie's Theory. MIE applied the Maxwell equations to a model in which a plane wave front meets an optically isotropic sphere with refractive index *n* and absorption index κ [28]. Integration gives the values of the absorption cross section Q_A and the scattering cross section Q_S; these dimensionless numbers relate the proportion of absorption and scattering to the geometric diameter of the particle. The theory has provided useful insights into the effect of particle size on the color properties of pigments.

Scattering is considered first. Here, the crucial parameter α in the Q_A and Q_S formulae is a relative measure of particle size because it is proportional to the particle diameter *D* and is inversely proportional to the wavelength λ. At a constant wavelength λ and for various relative refractive indices *n* (i.e., relative to the binder, $n = n_p/n_B$ where n_p and n_B are the refractive indices of the particle and binder, respectively), it gives the relationship between scattering and particle size (Fig. 7) [29]. If, on the other hand, the particle size *D* is kept constant, α denotes the relationship between the scattering and the wavelength (l/λ replaces *D* on the abscissa of Fig. 7). The well-marked maxima are typical, and their existence signifies (1) that an optimum particle size must exist with respect to lightening power [30], and (2) that for a given particle size, there must be a particular wavelength for maximum light scattering [31].

Figure 7. Scattering of white pigments as a function of particle size (λ = 550 nm)

a) Rutile; b) Anatase; c) Zinc sulfide; d) Zinc oxide; e) White lead; f) Barium sulfate

The first relationship can be used to predict the optimum particle size of white pigments (Table 7). The second relationship explains, for example, how white pigments in gray color mixtures can produce colored undertones as a result of selective light scattering (see Section Color Measurement).

Table 7. Refractive indices and optimal particle sizes of some white pigments (λ = 550 nm) calculated according to the van de Hulst formula [29]

Pigment	Formula	Mean refractive index		Optimal particle size (relative to binder) D_{opt}, µm
		Vacuum	Binder	
Rutile	TiO_2	2.80	1.89	0.19
Anatase	TiO_2	2.55	1.72	0.24
Zinc blende	α-ZnS	2.37	1.60	0.29
Baddeleyite	ZrO_2	2.17	1.47	0.37
Zincite	ZnO	2.01	1.36	0.48
Basic lead carbonate		2.01	1.36	0.48
Basic lead sulfate		1.93	1.30	0.57

The consequences of Mie's theory for *absorption* (i.e., for tinting strength) are now considered. Calculations from Mie's theory, using the relative refractive index *n* and the absorption index κ, are given in Figure 8 [32]. The parameter α on the abscissa can once more be taken as a relative measure of the particle size. The following conclusions may be drawn:

1. For very small particles, the absorption is independent of the particle size, and hence any further reduction in particle size does not produce additional absorption.
2. With increasing absorption index κ, the absorption of very small particles increases.
3. Absorption values for large particles are approximately equal for all relative refractive indices *n* and absorption indices κ, and decrease hyperbolically.
4. The top curve in Figure 8 applies to pigments with a high absorption index κ and low refractive index *n* (e.g., carbon black) and shows that the optimal particle size lies below a given limit.
5. The lowest curve applies to pigments with a small absorption index κ and high relative refractive index *n*, as is usually the case with inorganic pigments (e.g., red iron oxide). Here, there is a distinct maximum [11], [16].

Figure 8. Absorption as a function of particle size

The above relationships (Fig. 8) show that the optical pigment properties depend on the particle size *D* and the complex refractive index $n^* = n\,(1 - i\,\kappa)$, which incorporates the real refractive index *n* and the absorption index κ. As a result, the reflectance spectrum and hence the color properties of a pigment can be calculated if its complex refractive index, concentration, and particle size distribution are known [33]. Unfortunately, reliable values for the necessary optical constants (refractive index *n* and absorption index κ) are lacking. These two parameters generally depend on the wavelength and, owing to the optical anisotropy of most pigments, on the illuminant and viewing direction. In pigments with a high absorption, the refractive index shows “anomalous dispersion”. Refractive indices of inorganic pigment materials are given at selected wavelengths in Tables 7 and 8. However, these values were measured on large crystals, and not on pigment particles. Unfortunately, no direct methods exist for

determining n and κ in colored inorganic pigments.

Table 8. Refractive indices of important colored inorganic pigments [86]

Mineral	Formula	Wavelength λ, nm	Refractive index		
			n_ω n_α	n_ε n_β	n_γ
Bismuth vanadate	$BiVO_4$	670	2.45 [a]		
Cobalt blue	$CoAl_2O_4$	(blue)	1.74		
Eskolaite	α-Cr_2O_3	671	2.5 [a]		
Greenockite	CdS	589	2.506	2.529	
Goethite	α-FeOOH	589	2.275	2.409	2.415
Hematite	α-Fe_2O_3	686	2.988	2.759	
Carbon [b]	C	578	1.97		
Crocoite	$PbCrO_4$	671	2.31	2.37	2.66
Magnetite	Fe_3O_4	589	2.42		
Red lead	Pb_3O_4	671	2.42		
Ultramarine [c]			1.50		

[a] Mean refractive index.
[b] For carbon arc lamps.
[c] Formula is $[AlSiO_4]_6(SO_4)(S,Cl)_2(Na,Ca)_8$.

1.3.2. *Color Measurement*

General. Two methods are used for color measurement: the tristimulus method using a three-filter colorimeter and the spectral method using a reflectance spectrophotometer (⟶ Dyes, General Survey – Color Measurement and Colorant Formulation), however, the three-filter colorimeters are gradually being displaced by spectrophotometers Manufacturers have developed three-filter reflectometers and recording spectrophotometers. Instruments are continuously being improved due to technological advances. Photometer illuminating/viewing geometries are standardized as methods A and B, and are designed to suit the individual application (see Section Test Methods). For standards, see Table 1 ("Color Differences, Conditions/Evaluation. . .").

Method A. The geometry d/8 (diffuse illumination, viewing from an angle of 8°) or 8/d (illumination from an angle of 8°, diffuse viewing) — including specular reflection — enables total surface reflection and reflection from the interior of a sample to be measured. An amount representing the surface reflection has to be subtracted from the measured value. Thus, measured color variations can be ascribed to differences or changes of the colorants in the interior of the sample.

Method B. Here, color differences in samples are evaluated in almost the same way as in visual evaluation by exclusion of gloss effects. Suitable geometries are d/8, d/0, 8/d, and 0/d with a gloss trap, and 45/0 and 0/45.

After the color of the sample and reference pigments has been measured, color differences are usually calculated by transformation of the X, Y, and Z values into the CIELAB system to calculate color differences (see ⟶ Dyes, General Survey – Chromaticity Diagram, ⟶ Dyes, General Survey, ⟶ Dyes, General Survey – Calculation of Color Differences). Color measurement results of black and white pigments can be expressed more simply because they only amount to a determination of the relative color undertone. For this, the environment of the reference pigment is divided into eight sectors, these being filled with color names from "red" to "violet". The octant in which the CIELAB color position of the sample is located is found by calculation.

When colored or black systems are reduced with white pigments, an undertone is observed, which is a particle-size effect of the white pigment (see Section Fundamental Aspects). These undertones can be conveniently expressed as CIELAB color differences. The effects can, however, also be measured by using the difference $R_z - R_x$ between the values obtained with the blue and red tristimulus filters. The undertone measured in this way depends on the lightness, and has a maximum at Y = 41.4. The lightness of a gray paste should therefore have this value to ensure that undertone differences between white pigments are comparable [34], [35].

Measured color differences are only true (i.e., significant) when they are not falsified by measuring errors. A *significance* test standard (see Table 1, "Color differences, significance") has been developed to check this [35]. The numerical value of a color difference must be higher than a critical value, which is statistically calculated using the standard deviation.

Problems concerning the *acceptance* (tolerance) of color differences (e.g., in production quality control or in computer color matching) should also be solved by mathematical statistics [16].

The *gloss* of pigmented coatings is not a true pigment property. The pigment can, however, influence the luster quality, mainly via its dispersing properties (see Section Test Methods). The degree of gloss of a coating can range from high gloss (specular reflection) to an ideally matt surface (complete scattering). *Gloss haze* is due to a disturbance of specular reflection: the reflected objects appear as seen through a veil, this is caused by halation effects. Gloss retention is discussed in Section Fundamental Aspects , a method of gloss measurement is described in Section Test Methods. Special problems arise in the measurement of black [36] and fluorescent pigments [37].

Methods of Determination. *Lightness*. The white pigment powder is compressed in a suitable powder press to give an even, matt surface. The CIE tristimulus value Y is measured with color measuring equipment. For standards, see Table 1 ("Lightness"). Apparatus: spectrophotometer or tristimulus colorimeter, powder press, white standard.

Full Shade. Full-shade systems are media that contain only a single pigment. The color of the full-shade system in an optically infinitely thick (opaque) coating is referred to as full shade. The *mass tone* denotes the color obtained when the pigmented medium is applied as a layer that does not hide the substrate completely (e.g., on a white substrate). Evaluation can be carried out visually or by color measurement. For standards, see Table 1 ("Color in full-shade systems"). Apparatus: spectrophotometer or tristimulus colorimeter.

Color Difference. The computer printout in Figure 9 shows the CIELAB color positions of a reference pigment and a test sample: the color difference ΔE^*_{ab}, and the derived differences (Section Fundamental Aspects), i.e., lightness difference ΔL^*, chroma difference ΔC^*_{ab}, and hue difference ΔH^*_{ab}. The color difference of colored pigments in reduction can be similarly determined, including the "color difference after color reduction" which arises when tinting strength matching is carried out (see Section Tinting Strength, Lightening Power, and Scattering Power). An improved color difference formula takes into account the fact that chroma and hue differences can themselves depend on the chroma [16].

Figure 9. CIELAB color differences between two yellow iron oxide pigments

Undertone of Near-White Samples and Gray Undertones. The undertone of an almost uncolored sample is the small amount of color by which the color of a sample differs from ideal white or achromatic material. It is described by hue and chroma. The distance and direction of the CIELAB color position of the test sample (a^*_T, b^*_T) from the achromatic position (0, 0) are used to characterize the hue. The *relative undertone* is expressed by the distance and direction between the CIELAB color position of the test sample (a^*_T, b^*_T) and that of the reference pigment (a^*_R, b^*_R). In both cases, the distance is expressed by a figure and the direction by a color name. For standards, see Table 1 ("Hue relative of near white specimens"). Apparatus: spectrophotometer or tristimulus colorimeter for determining the CIE tristimulus values X, Y and Z with standard illuminants D 65 or C. With a computer, the color name can be printed out instead of the number of the octant (for example, see Fig. 10).

Figure 10. Undertone of two nearly white samples (TiO_2 pigments)

1.3.3. *Tinting Strength, Lightening Power, and Scattering Power*

The *tinting strength* is a measure of the ability of a colorant to confer color to a light-scattering material by virtue of its absorption properties. The *lightening power* can be considered as the tinting strength of a white pigment, and is a measure of its ability to increase the reflectance of an absorbing (black or colored) medium by virtue of its scattering power. Tinting strength is expressed as the mass ratio in which the reference pigment (mass, m_R) can be replaced by the test pigment (mass, m_T) to give the same color quality in a white system. Analogously, lightening power is the mass ratio in which the reference pigment can be replaced by the test pigment to give the same lightness in a colored system. Thus, the same equation defines tinting strength and lightening power:

$$P = (m_R/m_T)_{\Delta Q=\text{const}}$$

where ΔQ = const expresses the tinting strength matching. Both parameters are yield properties; if, for example, tinting strength is doubled, only half the weight of pigment is required. Optical properties can therefore provide information about the economic performance of a colored pigment ("value for money"). Testing of tinting strength and lightening power can be rationalized by means of the Kubelka – Munk theory (see Section Fundamental Aspects).

Tinting Strength. Within certain limits, relative tinting strength can be interpreted as the ratio of the absorption coefficients of equal masses of test and reference pigments. This procedure avoids visual matching of the test and reference pigments employed in a previously used method (tinting strength matching). For standards, see Table 1 ("Tinting strength, relative"). Materials and apparatus: white paste, spectrophotometer or tristimulus photometer.

In the determination of the tinting strength, specification of the matching between the test and the reference pigments is extremely important [38]. Since the criterion used for matching greatly influences the value of the tinting strength, it is not permissible to speak of tinting strength purely and simply. There are as many tinting strength values as there are matching criteria. In the German Standard, the following criteria are permitted:

1. The lowest of the three CIE tristimulus values *X, Y* and *Z*
2. The CIE tristimulus value *Y*
3. The depth of shade (see Section Light Stability).

When determining the tinting strength of inorganic pigments, the tristimulus value *Y* (lightness) is usually used [38].

Another standard method uses depth of shade as the matching criterion (FIAF method), but it is employed almost exclusively for testing organic pigments. This method can be applied by means of the "principle of spectral evaluation" (see Section Hiding Power and Transparency) [39], which uses the wavelength-dependent Kubelka – Munk coefficients $S(\lambda)$, $K(\lambda)$ to calculate the match [40]. The tinting strength for all other matching criteria can be determined by applying the principle of spectral evaluation. (For tinting strength in cement, see Section Miscellaneous Pigment – Binder Systems; for change in tinting strength, see Section Dispersing Behavior in Paint Systems).

Lightening Power. If the gray paste method is used to determine the lightening power (for standards, see Table 1, "Lightening power of white pigments"), the concentration at which the white pigment should be assessed has to be agreed between the intended parties in accordance with the type of application [41]. This process is especially recommended for the routine testing of pigments because the lightening power, the relative scattering power (see below), and the undertone can be determined with the same gray milling paste of the test pigment.

The method can be rationalized by means of the Kubelka – Munk theory. For standards, see Table 1 ("Tinting strength, relative: Photometric").

Relative Scattering Power. For standards, see Table 1 ("Scattering power, relative"). The relative scattering power *S* is the ratio of the scattering power S_T of the test white pigment to the scattering power of a white reference pigment S_R [42]. It can be determined in two ways:

1. *Black-Ground Method*. The relative scattering power is determined from the tristimulus values Y of the pigmented medium applied in various film thicknesses to black substrates. Compared with the gray paste method, the black-ground method has the advantage that it is not restricted to any particular test medium. Apparatus: spectrophotometer or tristimulus colorimeter.
2. *Gray Paste Method.* The relative scattering power is determined from the tristimulus values *Y* of gray pastes. The method has the advantage of being less time consuming than the black-ground method. The results of the two methods are not, however, generally in agreement. Materials and apparatus: black paste, spectrophotometer or tristimulus colorimeter.

1.3.4. *Hiding Power and Transparency*

The definition of hiding power is based on a black and white contrasting support upon which the film of coating is applied. The thickness *h* of the applied film is determined at the point at which the contrasting surface just disappears, as judged by eye. The film thickness (mm) which fulfils this condition is called the *hiding thickness*. Its reciprocal, the *hiding power* ($mm^{-1} = m^2/L$) is, like tinting strength, an indicator of yield because it gives the area (m^2) that can be covered up with 1 L of applied paint.

This traditional visual testing method has been improved by the use of a photometer and a colorimetric criterion to evaluate the hiding film thickness, e.g., $\Delta E^*_{ab} = 1$ for equally thick films applied to black and white backgrounds. The method can, however, be further rationalized. In this method only a single coating has to be prepared. The total reflectance spectrum is measured and after measuring the film thickness, the spectral scattering and absorption coefficients $S(\lambda)$ and $K(\lambda)$ are calculated at selected wavelengths (e.g., at intervals of 10 nm) by the Kubelka – Munk method. Once these values are known, the expected reflectances over black and white at the chosen wavelengths of the spectrum can be calculated for a given film thickness. Using the CIE and CIELAB systems, the CIELAB position of a color which would have this spectrum is calculated. This provides an iteration method for determining the film thickness at which the hiding power criterion $\Delta E^*_{ab} = 1$ is satisfied [39], [43], [44]. This principle of spectral evaluation [39] is the key to handling test methods based on the visual matching of two color samples (see also "Transparency" and "Tinting Strength", Section Tinting Strength, Lightening Power, and Scattering Power).

The *transparency* of a pigmented system denotes its ability to scatter light as little as possible. (see Table 1) The color change of a transparent pigmented system when applied to a black substrate has to be very small; the lower the color change, the higher is the transparency [45]. Measurement of transparency is important for assessing transparent varnishes and printing inks.

Hiding Power. The hiding criterion is an agreed color difference between two contrasting areas of a coated contrast substrate. The hiding power can be determined and expressed as D_V (m^2/L) or D_m (m^2/kg), which give the area (m^2) of the contrasting substrate that can be coated with 1 L or 1 kg, respectively, of the pigmented medium when the hiding criterion is satisfied. Layers of various thicknesses or mass-to-area ratios of the test material are applied to the contrast background. The color difference ΔE^*_{ab} between the two contrasting areas is determined by color measurement on each of the layers. The color difference is plotted against the reciprocal of the film thickness (mm^{-1}) or the reciprocal of the mass to area ratio (m^2/kg). The hiding power D_V (m^2/L) or D_m (m^2/kg) at the hiding criterion (e.g., $\Delta E^*_{ab} = 1$) is then obtained from the diagram (Fig. 11). For standards, see Table 1 ("Hiding power"). Apparatus: spectrophotometer or tristimulus colorimeter, film thickness measuring equipment.

Figure 11. Determination of the hiding power of a yellow iron oxide pigment

A modern well equipped color measurement laboratory can use the "principle of spectral evaluation" described above [39] to simulate this procedure with a computer. The thickness of the hiding film can then be calculated in advance from the reflectance curves of a single film on a black/white substrate at a known film thickness.

Hiding Power of Achromatic Coatings. Equally thick coatings of the pigmented coating material are applied to a black and white background, and their reflectances measured with a photometer after drying. The hiding power is then calculated from the reflectances on black and white substrates and the film thickness. The hiding criterion is $\Delta L^* = 1$, in analogy with that for colored pigments [14]. The use of hiding power as a basis for assessing the economy and effectiveness of pigments is described in [46]. Apparatus: spectrophotometer or tristimulus colorimeter, black and white glass plates.

Transparency. Transparency is expressed quantitatively as the transparency number. This is defined as the reciprocal of the increase in color difference ΔE^*_{ab} on a black substrate obtained on increasing the film thickness *h* of the pigmented medium. The transparency number has the unit mm (= L/m^2). It indicates the number of liters of

pigmented medium needed to coat 1 m^2 of a black substrate in order to obtain a color difference of ΔE^*_{ab} =1 relative to this substrate. In a simplified method the transparency number can be determined by evaluating one or two points on the straight part of the $\Delta E^*_{ab}(h)$ curve. A computer method is more exact, furthermore calculations can be made using the spectral "principle of spectral evaluation." For standards, see Table 1 ("Transparency").

1.4. Stability Towards Light, Weather, Heat, and Chemicals

1.4.1. *Fundamental Aspects [47]*

Many pigmented systems show typical color or structural changes when subjected to intense radiation or weathering [48]. The best-known of these are yellowing [49], chalking, and loss of gloss. These processes involve photochemical reactions in which the pigment can act as a catalyst or in which the pigment itself undergoes chemical changes.

Inorganic pigments are chemically very stable and are classed as one of the most stable coloring matters. This is especially true for oxide pigments which often have a highly protective effect on the substrate [50]. Apart from the purely mechanical stabilization imparted by the pigment, this protective effect can give a coating an increased economic advantage. On the other hand, sulfide pigments can be oxidized by the atmosphere to form sulfates which can be washed away by rain [51].

The photochemical processes that take place when TiO_2-containing coatings undergo chalking have been elucidated [52]. The shorter wavelength radiation of sunlight acts on rainwater and atmospheric oxygen to form extremely reactive radicals (·OH, HO_2·) that cause deterioration of the coating matrix by oxidative attack. Titanium dioxide pigments may be stabilized by reducing the number of radical-producing hydroxy groups on the surface of the TiO_2 particles (e.g., by doping with zinc oxide). Alternatively, coatings of oxide hydrates are produced by aftertreatment of the pigment surface to give "reaction walls" on which the radicals are destroyed [53].

Continuous breakdown of the binder leads to the loss of gloss. Surface gloss gives an attractive appearance and is usually desired, it is obtained by ensuring that the pigment particles are well dispersed. The stability of gloss to weathering is therefore of great importance. If breakdown of the binder is so extensive that the pigment may be loosened, *chalking* takes place. Chalking is defined as loosening of pigment or extender particles following destruction of the binder at the surface. For standards, see Table 1 ("Coating materials").

Resistance to light and weather generally depend on the chemical composition, structure, defects, particle shape and size, and concentration of the pigment [54]. However, these properties also depend on the medium in which the pigment is used. Testing is carried out by open-air weathering, accelerated weathering, and chemical test methods.

Accelerated weathering is carried out in special weathering devices (e.g., Weatherometer, Xenotest) which simulate exposure to sunlight and periods of rain. The spectral composition of the light used (Fig. 12) should match the "global radiation" in temperate latitudes (global radiation denotes the sum of the direct solar radiation and indirect radiation from the sky). However, accelerated tests only allow limited conclusions to be drawn about light and weather resistances because it is not possible to accurately simulate all climatic conditions, their combinations and sequences, or sudden changes. Even so, natural weathering tests are not without problems: weather cannot be standardized, and a "uniform" weather therefore does not exist [55], [56]. Weathering results, even from successive years, can thus vary considerably [57]. Weather also varies with the geographical coordinates. For standards, see Table 1 ("Climates: Normalized"); the earth is classified into climatic regions and weathering adjustment scales exist [58].

Figure 12. Spectral energy distribution of daylight phase D65 with permitted range of deviation (shading)

None of the chemical methods (e.g., mandelic acid or methanol test) gives a perfect indication of weather resistance. Most of them only measure partial qualities of the photochemical reactivity [59].

The oxide pigments have the highest *heat stability*, followed by the sulfide pigments which can even be used in enamels and glass melts (e.g., cadmium pigments). The oxide hydroxides and carbonates are less heat stable. Thermal stability is of great importance for modern coating techniques (e.g., for stoving finishes and other products requiring high temperatures). The heat resistance of a pigment primarily depends on the binder and the duration of heating. It is conveniently determined by observing hue changes in the pigmented coating system after a defined heat treatment, e.g., with white coatings yellowing occurs. For standards, see Table 1 ("PVC").

The *chemical resistance* of inorganic pigments, especially oxide pigments, is in general very high [60]. Other fastness properties such as overspray fastness, fastness to blooming, and fastness to plasticizers are of more relevance to organic pigments. For corrosion inhibiting (anticorrosive) pigments, see Section Anticorrosive Pigments.

1.4.2. *Test Methods*

1.4.2.1. *Light Stability*

Accelerated Tests. Light stability is a material property. It is defined as the resistance of coatings towards changes caused by the action of global radiation (daylight phase: standard illuminant D 65), possibly in the presence of moisture. In coatings, light and moisture can lead to chalking and changes in gloss and color. For standards, see Table 1 ("Light stability"). Apparatus: testing cabinets, equipment for wetting the test plates, equipment for producing air flow.

Evaluation of Color Changes (see Section Color Measurement). Color changes are differences in lightness, chroma, and hue such as exist between identical samples with different histories. Evaluation methods are particularly suitable for the determination and evaluation of color changes that occur following physical and chemical stresses on pigmented materials. The CIE tristimulus values *X, Y*, and *Z* of the samples or of different test locations on a sample are determined with a colorimeter . The CIELAB color difference is calculated for each sample or test location from the tristimulus values before and after the stress (see Section Color Measurement). Apparatus: spectrophotometer, tristimulus colorimeter.

Standard Depth of Shade. The depth of shade is a measure of the intensity of a color sensation. It increases with increasing chroma and generally decreases with increasing lightness. The colorfastness of colorations (e.g., textile dyeing) is dependent on depth of shade; the fastness properties of pigments or pigmented systems must therefore be tested at a predetermined depth of shade. This standard method therefore ensures that samples with standard depths of shade are used to determine the fastness properties of pigments or pigmented systems [61], [62]. For standards, see Table 1 ("Standard depth of shade"). Apparatus: spectrophotometer or tristimulus filter photometer with gloss trap. (For light stability in cement, see Section Miscellaneous Pigment – Binder Systems.)

1.4.2.2. *Weather Resistance*

The empirical tests described below determine the chalking and weathering differences between two pigments, but do not always give the true differences. Other test methods have therefore been developed, e.g., determination of mass losses on weathering (gravimetric test) [52].

Accelerated Tests. Weather resistance in an accelerated test is defined as the resistance of plastics towards changes caused by simulated open-air weathering (simulation of global radiation by means of filtered xenon arc radiation and periodic rain). After the weathering (measured by the product of intensity and duration), defined properties of the test sample are compared with those of an identical unweathered sample. Properties should be considered which are of practical importance, such as color or surface properties. For standards, see Table 1 ("Weathering in apparatus"). Apparatus: test chamber, rain and air humidification equipment, air flow equipment, radiation measuring equipment.

Degree of Chalking. The degree of chalking of a coating is measured by the quantity of loose pigment particles. It may be determined by three methods:

1. *Kempf Method.* For standards, see Table 1 ("Chalking degree: Kempf method"). Water-treated photographic paper is applied to the coating (with the humid gelatin side facing the coating surface) and pressed by means of a special stamp device. Loose pigment particles that are not attached to the binder, are picked up by the gelatin coating. The degree of chalking is judged visually (for scale of measurement see Table 1, "Test evaluation"). See also Section Methods of Determination. Apparatus: Kempf stamp equipment.
2. *Adhesive Tape Method.* For standards, see Table 1 ("Chalking degree; Adhesive tape method"). Loose pigment particles are picked up by transparent adhesive tape. The degree of chalking is determined from a reference scale (see Table 1, "Test Evaluation" and Section Methods of Determination) or by using a comparative scale that is agreed upon by the interested parties.
3. *Photographic Methods.* For standards, see Table 1 ("Chalking degree: Photographic method"). Chalking prints on paper are compared with photographic standards.

Assessment of Gloss. Gloss is not a purely physical quantity, it is also dependent on physiological and psychological factors. The usefulness of measured reflectance values lies in the possibility of detecting surface changes of the test sample and observing them over a long period. These changes can be produced by weathering, abrasion, and similar causes of surface wear, or by the method used to produce the surface. For standards, see Table 1 ("Reflectometer"). Apparatus: reflectometer with

incident light angles of 20°, 60°, or 85°. For standards see “Gloss” in Table 1.

Effects of Humid Climates. The specimen is exposed to warm air saturated with water vapor, with or without intermittent cooling to room temperature. The test is very suitable for assessing the corrosion resistance of metals, protective coatings, and composite materials in buildings. For standards, see Table 1 (“Climates: Containing evaporated water”). Apparatus: Kesternich condensation equipment.

1.4.2.3. *Heat Stability [63]*

Measured values of the heat stability of pigments depend on the type and duration of the heat applied, and also on the binder used. Low thermal stability in white coatings leads to yellowing, even when the unpigmented binder is resistant to yellowing. With colored coatings, changes in the hue of the pigmented binder can be measured colorimetrically (see Section Color Measurement). Standards only exist for special systems (e.g., hard and soft PVC; and cement, see Section Miscellaneous Pigment – Binder Systems). Thermal resistances of pigments are customarily quoted at two temperatures: (1) the maximum temperature at which the hue remains stable, and (2) the temperature at which a defined hue change is observed. For standards, see Table 1 (“Heat stability” and “Coloration of building materials”).

1.4.2.4. *Fastness to Chemicals [63]*

General chemical resistance can be classified as short-, medium-, or long-time resistances. Changes in the coating are assessed visually. For standards, see Table 1 (“Chemical resistance”). Apparatus: film thickness measuring equipment.

Resistance to Water in Sulfur-Dioxide-Containing Atmospheres. For standards, see Table 1 (“Corrosion testing; SO_2” and “SO_2 resistance”). General conditions are standardized for exposing samples to a varying climate where water condenses in the presence of sulfur dioxide, so that tests in different laboratories give comparable results. The test allows rapid detection of defects in corrosion-inhibiting systems.

Furthermore, a method for determining the colorfastness of pigments in binders in the presence of sulfur dioxide is also prescribed. The test is carried out simultaneously on ten identical samples and consists of three cycles. Apparatus: condensation equipment.

Salt Spray Fog Test with Sodium Chloride Solutions. The sample is sprayed continuously with a 5 % aqueous sodium chloride solution. There are three variations of the test: the salt spray fog test, the acetic acid salt spray test, and the copper chloride – acetic acid salt spray test.

For standards, see Table 1 (“Corrosion testing: NaCl”). Materials and apparatus: spray chamber, test solutions (5 % NaCl solutions).

Resistance to Spittle and Sweat. This test indicates whether a pigment on a child's colored toy is likely to be transferred to the mouth, mucous membranes, or skin during use. Strips of filter paper are wetted with $NaHCO_3$ and NaCl solutions and pressed against the test samples. The discoloration of the paper is judged visually. For standards, see Table 1 (“Spittle/sweat resistance”).

1.5. Behavior of Pigments in Binders

1.5.1. *Fundamental Aspects [64], [65]*

A pigment – binder dispersion is a suspension before it is dried; after drying it is a solid sol. In pigment – binder systems, the concepts and laws of colloid chemistry therefore apply. The dispersing of pigments and extenders in binders is an extremely complex process of a series of steps that can be interlinked [64], see also ⟶ Paints and Coatings – Production Technology. Dispersing involves the following steps:

1. *Wetting.* Removal of the air from the surface of the pigment particles and formation of a solvate layer [66], [67].
2. *Disintegration.* Breaking up of pigment agglomerates with external energy (e.g., by dispersing equipment).
3. *Stabilization.* Maintenance of the disperse state by creating repulsive forces between the particles (e.g., by coating them with solvate layers). These forces must be greater than the van der Waals attraction forces [68] that cause flocculation [69], [70].

The degree of dispersing usually has a large influence on the properties of the coating system [71], [72]. Some of these properties depend strongly on the degree of dispersing, and are therefore used to measure dispersibility. For standards, see Table 1 (“Ease of dispersion”). Examples are viscosity (pigment – binder dispersions always show non-Newtonian behavior properties before drying) and color properties, especially hue, tinting strength, gloss, and gloss haze [73] (see Sections Color Properties and Stability Towards Light, Weather, Heat, and Chemicals).

In many systems, tinting strength depends so highly on the degree of dispersing that the rate of tinting strength development can be taken as a direct measure of dispersibility [74-77] (see Section Dispersing Behavior in Paint Systems). The numerical values of the half-life times (characterizing the dispersibility) and of the increases in strength (characterizing the strength potential) depend on the binder and the dispersing equipment used.

In systems where different pigments are combined (e.g., white and colored pigments), segregation effects can occur which change the optical appearance (flooding [79]). Flooding can be counteracted by preflocculation of the pigments with suitable gelling agents, and in some cases by addition of extenders (see ⟶ Paints and Coatings – Wetting and Dispersing Additives).

In solvent-containing systems with several pigments, but also in full-shade systems, color changes (rub-out effect) can take place due to flocculation, especially if the systems are subjected to mechanical stress during application and drying. The flocculation tendency can be determined by means of the “rub-out test” (see ⟶ Paints and Coatings – Wetting and Dispersing Additives).

1.5.2. *Test Methods*

1.5.2.1. *Pigment – Binder Interaction*

Oil Absorption. The oil absorption gives the mass or volume of linseed oil required to form a coherent putty-like mass with 100 g pigment under specified conditions. The mixture should just not smear on a glass plate. For standards, see Table 1 (“Oil absorption”). Materials and apparatus: rough glass plate, spatula with steel blade, raw linseed oil.

Binder Absorption, Smear Point, and Yield Point [80]. Smear point and yield point are used to determine the binder needed to formulate a suitable millbase for grinding by dissolvers, roll mills, ball mills, attritors, sand mills, and pearl mills. The amount of binder is given in volume or mass units. Apparatus: rough glass plate, spatula with steel blade.

Viscosity. Viscosity is a useful parameter for coatings applied by brushing. It is determined by measuring the torque applied to a rotating cylinder or disk in or on the surface of a suspension. This method is applicable to Newtonian and non-Newtonian systems. In non-Newtonian suspensions, the apparent viscosity is obtained by dividing the shear stress by the shear rate. The viscosities provide information about the force required in the initial brushing phase of a coating. For standards, see Table 1 (“Viscosity”). Apparatus: cone/plate or rotating cylinder viscometer.

Fineness of Grind. The grind gauge (grindometer) consists of a steel block with a groove. The depth of the groove at one end is approximately twice the diameter of the largest pigment particle, and decreases continuously to zero at the other end. The sample is placed at the deep end of the groove and drawn to the other end with a scraper. The depth at which a large number of particles become visible on the surface of the pigment – binder system as pinholes or scratches is read off from a scale graduated in micrometers. For standards, see Table 1 (“Fineness of grind”). Apparatus: Hegman's grindometer gauge (block and scraper).

1.5.2.2. *Dispersing Behavior in Paint Systems*

Low-Viscosity Media. The time is measured that is required to produce a homogeneous suspension of particles in the dispersion medium using an oscillatory shaking machine equipped with several containers. Not only can small quantities of the millbase with the same composition be tested (as with other types of apparatus), but various millbases can also be tested under the same conditions. A low-viscosity alkyd resin system of the stoving or oxidatively drying type can be used as a test medium. For standards, see Table 1 (“Ease of dispersion: Oscillatory shaking machine”).

High-Viscosity Media (Pastes). The dispersion properties are determined with an automatic muller. The advantage is that small amounts of material can be simply tested under reproducible conditions. For standards, see Table 1 (“Ease of dispersion: Automatic muller“).

Development of Fineness of Grind. The quantity measured is the dispersing effect needed to achieve a given fineness of grind. Samples of the product are taken at various stages of the dispersion process and the fineness of grind is determined with a grindometer gauge. The method is used to compare diverse millbases material types of dispersing equipment, or dispersing methods used with the same pigment. For standards, see Table 1 (“Fineness of grind”).

Change in Tinting Strength, Half-Life Times, and Increase in Strength. For standards see Table 1 (“Change in strength”). Dispersibilities of pigments may be compared by means of their dispersing resistance, dispersing equipment may be characterized by means of dispersing effects. Measurement can be based on determination of half-life times in relation to the final tinting strength. The increase in strength, however, only gives the difference between the initial and final tinting strength [77]. Half-life times are functions of the dispersing rate. They are only valid for a given combination of dispersing equipment, dispersing process, and medium. Samples are taken from the millbase at specified stages in the dispersing process and mixed with a white paint based on the same binder material, or with a compatible white paste. The tinting strength is then

determined (see Section Tinting Strength, Lightening Power, and Scattering Power) and a graph is drawn; development of tinting strength is plotted against the dispersion stages (Fig. 13) [81].

Figure 13. Change in tinting strength as a function of dispersing time

A new method allows to calculate the three dispersion velocities [78]:

- Size reduction vs. large particles
- Size reduction vs. small particles
- Size reduction vs. the vessel walls/grinding bodies

Surprisingly, the dispersion rate for the size reduction vs. small particles is negative, which indicates that no reduction but reagglomeration takes place. This new method requires two millbases with different pigment volume concentration and a computer.

Pigment Volume Concentration (PVC) and Critical Pigment Volume Concentration (CPVC). The pigment volume concentration (σ) is the fractional volume of pigment in the total solids volume of the dry paint film:

$$\sigma = \frac{V_p}{V_p + V_b}$$

where V_p is the pigment volume and V_b the binder volume. The *PVC* [82] is determined by separating the pigment fraction from a weighed paint sample by, for example, extracting the (liquid) binder with suitable organic solvents or solvent mixtures (sometimes using a centrifuge) or using combustion methods (sometimes including fuming with sulfuric acid) and analysis of the residue [83].

Under *CPVC* conditions, the pigment particles are at a maximum packing density, and the interstices are completely filled with binder. With smaller amounts of binder, the interstices are incompletely filled. The *CPVC* thus represents a pigment concentration boundary at which abrupt changes in the properties of the film occur.

The methods of determining the *CPVC* [84] are divided into two groups:

1. Methods based on the observation of a sudden change in properties in a series of *PVCs* (e.g., ion permeability, permeability to water vapor, color, gloss stability after coating with a silk-luster paint)
2. Methods based on the experimental production of the dense pigment packing typical of *CPVC*, e.g., by means of oil absorption, filtration, vacuum filtration, or by measuring the volume of the supercritical film

Measurement of Deposit. Common methods used to measure sediments are manual testing, sedimentation balance, radioactive methods, dipping of bodies, and probe tools.

The special measuring equipment known as the Bayer system [85], can test for deposits with great accuracy and good reproducibility. The force acting on a needle probe is measured which penetrates into the coating material from above.

1.5.2.3. *Miscellaneous Pigment – Binder Systems*

Plastics. Specifications for thermoplastics are given in Table 1 ("Thermoplastics"). Specifications for poly(vinyl chloride) are also listed ("PVC"). These specifications include methods for producing basic mixtures for testing pigments in PVC and for specimen preparation. A method is described for determining bleeding, i.e., the migration of coloring matter into a material in contact with the sampling equipment. Special procedures are also included for the determination of heat stability and increase in strength caused by cold rolling.

Building Materials. For standards, see Table 1 ("Coloration of building materials"). The following tests are prescribed for assessing the suitability of a pigment for coloring cement and lime-bonded building materials:

Relative tinting strength
Colorfastness in cement
Colorfastness in lime
Lightfastness
Heat stability
Influence of the pigment on hardness of the building material
Influence of the pigment on setting properties

Paper and Board. For standards, see Table 1 ("Opacity" and "Transparency"). Methods of measurement are specified for the reflectance of paper and board (nonfluorescent), and the opacity or transparency of paper (to measure the transmitted light).

[Top of Page]

2. White Pigments

Jürgen Kischkewitz, Peter Woditsch, Axel Westerhaus, Wolf-Dieter Griebler, Marcel De Liedekerke

White pigments include TiO_2, zinc white (ZnO), zinc sulfide, lithopone (a mixed pigment produced from zinc sulfide and barium sulfate), and white lead (basic lead carbonate). The optical properties of white pigments are a result of their low light absorption and their strong, mainly nonselective, scattering of light.

2.1. Titanium Dioxide

Titanium dioxide [13463-67-7], TiO_2, M_r 79.90, occurs in nature in the modifications rutile, anatase, and brookite. Rutile and anatase are produced industrially in large quantities and are used as pigments and catalysts, and in the production of ceramic materials.

Titanium dioxide is of outstanding importance as a white pigment because of its scattering properties (which are superior to those of all other white pigments), its chemical stability, and lack of toxicity. Titanium dioxide is the most important inorganic pigment in terms of quantity, 3.2×10^6 t were produced in 1995. World production of titanium dioxide pigment is shown in Table 9 [87-89].

Table 9. World production of TiO_2 pigment

Year	Sulfate process		Chloride process		Total
	10^3 t/a	%	10^3 t/a	%	10^3 t/a
1965	1254	90.3	135	9.7	1389
1970	1499	77.4	437	22.6	1936
1977	1873	72.3	716	27.7	2589
1988	1781	60.2	1178	39.8	2959
1995	1481	46	1739	54.0	3220
2000*	1540	40	2310	60.0	3850

* Estimated.

2.1.1. *Properties [90], [91]*

Physical Properties. Of the three modifications of TiO_2, rutile is the most thermodynamically stable. Nevertheless, the lattice energies of the other phases are similar and hence are stable over long periods. Above 700 °C, the monotropic conversion of anatase to rutile takes place rapidly. Brookite is difficult to produce, and therefore has no value in the TiO_2 pigment industry.

In all three TiO_2 modifications one titanium atom in the lattice is surrounded octahedrally by six oxygen atoms, and each oxygen atom is surrounded by three titanium atoms in a trigonal arrangement. The three modifications correspond to different ways of linking the octahedra at their corners and edges. Crystal lattice constants and densities are given in Table 10.

Table 10. Crystallographic data for TiO_2 modifications

Phase	CAS registry no.	Crystal system	Lattice constants, nm			Density, g/cm^3
			a	*b*	*c*	
Rutile	[1317-80-2]	tetragonal	0.4594		0.2958	4.21
Anatase	[1317-70-0]	tetragonal	0.3785		0.9514	4.06
Brookite	[12188-41-9]	rhombic	0.9184	0.5447	0.5145	4.13

Rutile and anatase crystallize in the tetragonal system, brookite in the rhombic system. The melting point of TiO_2 is ca. 1800 °C. Above 1000 °C, the oxygen partial pressure increases continuously as oxygen is liberated and lower oxides of titanium are formed. This is accompanied by changes in color and electrical conductivity. Above 400 °C, a significant yellow color develops, caused by thermal expansion of the lattice; this is reversible. Rutile has the highest density and the most compact atomic structure, and is thus the hardest modification (Mohs hardness 6.5 – 7.0). Anatase is considerably softer (Mohs hardness 5.5).

Titanium dioxide is a light-sensitive semiconductor, and absorbs electromagnetic radiation in the near UV region. The energy difference between the valence and the conductivity bands in the solid state is 3.05 eV for rutile and 3.29 eV for anatase, corresponding to an absorption band at < 415 nm for rutile and < 385 nm for anatase.

Absorption of light energy causes an electron to be excited from the valence band to the conductivity band. This electron and the electron hole are mobile, and can move on the surface of the solid where they take part in redox reactions.

Chemical Properties. Titanium dioxide is amphoteric with very weak acidic and basic character. Accordingly, alkali-metal titanates and free titanic acids are unstable in water, forming amorphous titanium oxide hydroxides on hydrolysis.

Titanium dioxide is chemically very stable, and is not attacked by most organic and inorganic reagents. It dissolves in concentrated sulfuric acid and in hydrofluoric acid, and is attacked and dissolved by alkaline and acidic molten materials.

At high temperature, TiO_2 reacts with reducing agents such as carbon monoxide, hydrogen, and ammonia to form titanium oxides of lower valency; metallic titanium is not formed. Titanium dioxide reacts with chlorine in the presence of carbon above 500 °C to form titanium tetrachloride.

Surface Properties of TiO_2 Pigments. The specific surface area of TiO_2 pigments can vary between 0.5 and 300 m^2/g depending on its use. The surface of TiO_2 is saturated by coordinatively bonded water, which then forms hydroxyl ions. Depending on the type of bonding of the hydroxyl groups to the titanium, these groups possess acidic or basic character [92], [93]. The surface of TiO_2 is thus always polar. The surface covering of hydroxyl groups has a decisive influence on pigment properties such as dispersibility and weather resistance.

The presence of the hydroxyl groups makes photochemically induced reactions possible, e.g., the decomposition of water into hydrogen and oxygen and the reduction of nitrogen to ammonia and hydrazine (see also Section Pigment Properties) [94].

2.1.2. *Raw Materials [95], [111]*

The raw materials for TiO_2 production include natural products such as ilmenite, leucoxene, and rutile, and some very important synthetic materials such as titanium slag and synthetic rutile. Production figures for the most important titanium-containing raw materials are listed in Table 11 [96]. Total production of titanoferrous raw materials, excluding that produced and consumed in the former Soviet Union and China, grew in 1994 to 3.69 × 10^6 t of contained TiO_2 [96]. Australia was the largest producer, followed by Africa, Canada, and Norway.

Table 11. Production of titanium-containing raw materials (1994)

Raw material	Location	Capacity, 10^3 t/a
Ilmenite*	Australia	1550
	Canada	1850
	Former Soviet Union	250
	India	280
	Norway	700
	Republic of South Africa	1500
	United States	320
	Others	450
	Total	7120
Rutile	Australia	216
	Former Soviet Union	30
	Republic of South Africa	90
	Sierra Leone	144
	Others	70
	Total	550
Synthetic rutile	Australia	417
	India	43
	Japan	10
	United States	140
	Total	625
Titanium slag	Canada	764
	Norway	170
	Republic of South Africa	773
	Total	625

* Includes ilmenite used in the production of titanium slag and synthetic rutile.

2.1.2.1. *Natural Raw Materials*

Titanium is the ninth most abundant element in the earth's crust, and always occurs in combination with oxygen. The more important titanium minerals are shown in Table 12. Of the natural titanium minerals, only ilmenite (leucoxene) and rutile are of economic importance. Leucoxene is a weathering product of ilmenite.

Table 12. Titanium minerals

Mineral	Formula	TiO_2 content, wt %
Rutile	TiO_2	92 – 98
Anatase	TiO_2	90 – 95
Brookite	TiO_2	90 – 100
Ilmenite	$FeTiO_3$	35 – 60
Leucoxene	$Fe_2O_3TiO_2$	60 – 90
Perovskite	$CaTiO_3$	40 – 60
Sphene (titanite)	$CaTiSiO_5$	30 – 42
Titanomagnetite	$Fe(Ti)Fe_2O_4$	2 – 20

The largest titanium reserves in the world are in the form of anatase and titanomagnetite, but these cannot be worked economically at the present time. About 95 % of the world's production of ilmenite and rutile is used to produce TiO_2 pigments, the remainder for the manufacture of titanium metal and in welding electrodes.

Ilmenite and Leucoxene. *Ilmenite* is found worldwide in primary massive ore deposits or as secondary alluvial deposits (sands) that contain heavy minerals. In the massive ores, the ilmenite is frequently associated with intermediary intrusions (Tellnes in Norway and Lake Allard in Canada). The concentrates obtained from these massive ores often have high iron contents in the form of segregated hematite or magnetite in the ilmenite. These reduce the TiO_2 content of the concentrates (see Table 13). Direct use of these ilmenites has decreased owing to their high iron content. A digestion process is employed to produce iron sulfate heptahydrate. In cases where iron sulfate is not required as a product, metallurgical recovery of iron from the iron-rich ilmenites and production of a titanium-rich slag are being increasingly used.

Table 13. Composition of ilmenite deposits (wt %)

Component	Tellnes (Norway)	Richard's Bay (Republic of South Africa)	Capel (Western Australia)	Quilon (India)
TiO_2	43.8	46.5	54.8	60.3
Fe_2O_3	14.0	11.4	16.0	24.8
FeO	34.4	34.2	23.8	9.7
Al_2O_3	0.6	1.3	1.0	1.0
SiO_2	2.2	1.6	0.8	1.4
MnO	0.3		1.5	0.4
Cr_2O_3		0.1	0.1	0.1
V_2O_5	0.3	0.3	0.2	0.2
MgO	3.7	0.9	0.15	0.9

The enrichment of ilmenite in beach sand in existing or fossil coastlines is important for TiO_2 production. The action of surf, currents, and/or wind results in concentration of the ilmenite and other heavy minerals such as rutile, zircon, monazite, and other silicates in the dunes or beaches. This concentration process frequently leads to layering of the minerals. Attack by seawater and air over geological periods of time leads to corrosion of the ilmenite. Iron is removed from the ilmenite lattice, resulting in enrichment of the TiO_2 in the remaining material. The lattice is stable with TiO_2 contents up to ca. 65 %, but further removal of iron leads to the formation of a submicroscopic mixture of minerals which may include anatase, rutile, and amorphous phases. Mixtures with TiO_2 contents as high as 90 % are referred to as *leucoxene*. Leucoxene is present in corroded ilmenite and in some deposits is recovered and treated separately. However, the quantities produced are small in comparison to those of ilmenite.

The concentrates obtained from ilmenite sand, being depleted in iron, are generally richer in TiO_2 than those from the massive deposits. Other elements in these concentrates include magnesium, manganese, and vanadium (present in the ilmenite) and aluminum, calcium, chromium, and silicon which originate from mineral intrusions.

Two-thirds of the known ilmenite reserves that could be economically worked are in China, Norway (both massive deposits), and the former Soviet Union (sands and massive deposits). On the basis of current production capacities, these countries could cover all requirements for ca. 150 years. However, the countries with the largest outputs are Australia (sands), Canada (massive ore), and the Republic of South Africa (sands). Other producers are the United States (sands, Florida), India (sands, Quilon), the Former Soviet Union (sands, massive ore), Sri Lanka (sands), and Brazil (rutilo e ilmenita do Brasil). In 1994 the production of ilmenite was ca. 1.2×10^6 t of contained TiO_2.

Rutile is formed primarily by the crystallization of magma with high titanium and low iron contents, or by the metamorphosis of titanium-bearing sediments or magmatites. The rutile concentrations in primary rocks are not workable. Therefore, only sands in which rutile is accompanied by zircon and/or ilmenite and other heavy minerals can be regarded as reserves. The world reserves of rutile are estimated to be 28×10^6 t, including the massive Piampaludo ore reserves in Italy, whose workability is in dispute.

As in the case of ilmenite, the largest producers are in Australia, the Republic of South Africa, and Sierra Leone. There is not enough natural rutile to meet demand, and it is therefore gradually being replaced by the synthetic variety. Compositions of typical rutile concentrates are given in Table 14.

Table 14. Composition of rutile deposits [97]

Rutile component	Content, wt %		
	Eastern Australia	Sierra Leone	Republic of South Africa
TiO_2	96.00	95.70	95.40
Fe_2O_3	0.70	0.90	0.70
Cr_2O_3	0.27	0.23	0.10
MnO	0.02		
Nb_2O_5	0.45	0.21	0.32
V_2O_5	0.50	1.00	0.65
ZrO_2	0.50	0.67	0.46

Al_2O_3	0.15	0.20	0.65
CaO	0.02		0.05
P_2O_5	0.02	0.04	0.02
SiO_2	1.00	0.70	1.75

Anatase, like rutile, is a modification of TiO_2. The largest reserves of this mineral are found in carboniferous intrusions in Brazil. Ore preparation techniques allow production of concentrates containing 80 % TiO_2, with possible further concentration to 90 % TiO_2 by treatment with hydrochloric acid [98]. The TiO_2 content of these mineral deposits is estimated at up to 10^8 t.

Ore Preparation. Most of the world's titanium ore production starts from heavy mineral sands. Figure 14 shows a schematic of the production process. The ilmenite is usually associated with rutile and zircon, so that ilmenite production is linked to the recovery of these minerals. Geological and hydrological conditions permitting, the raw sand (usually containing 3 – 10 % heavy minerals) is obtained by wet dredging (a). After a sieve test (b), the raw sand is subjected to gravity concentration in several stages with Reichert cones (d) and/or spirals (e) to give a product containing 90 – 98 % heavy minerals. This equipment separates the heavy from the light minerals (densities: 4.2 – 4.8 g/cm^3 and < 3 g/cm^3 respectively) [99].

Figure 14. The processing of heavy mineral sands

The magnetic minerals (ilmenite) are then separated from the nonmagnetic (rutile, zircon, and silicates) by dry or wet magnetic separation (f). If the ores are from unweathered deposits, the magnetite must first be removed. An electrostatic separation stage (h) allows separation of harmful nonconducting mineral impurities such as granite, silicates, and phosphates from the ilmenite, which is a good conductor. The nonmagnetic fraction (leucoxene, rutile, and zircon) then undergoes further hydromechanical processing (i) (shaking table, spirals) to remove the remaining low-density minerals (mostly quartz). Recovery of the weakly magnetic weathered ilmenites and leucoxenes is by high-intensity magnetic separation (j) in a final dry stage. The conducting rutile is then separated from the nonconducting zircon electrostatically in several stages (l). Residual quartz is removed by an air blast.

2.1.2.2. *Synthetic Raw Materials*

Increasing demand for raw materials with high TiO_2 contents has led to the development of synthetic TiO_2 raw materials. In all production processes, iron is removed from ilmenites or titanomagnetites.

Titanium Slag. The metallurgical process for removing iron from ilmenite is based on slag formation in which the iron is reduced by anthracite or coke to metal at 1200 – 1600 °C in an electric arc furnace and then separated. Titanium-free pig iron is produced together with slags containing 70 – 85 % TiO_2 (depending on the ore used) that can be digested with sulfuric acid because they are high in Ti^{3+} and low in carbon. Raw materials of this type are produced in Canada by the Quebec Iron and Titanium Corporation (QIT), in the Republic of South Africa by Richard's Bay Minerals (RBM), and to a smaller extent by Tinfos Titan and Iron K.S. (Tyssedal, Norway). Total slag production in 1994 was 1.4 × 10^6 t of contained TiO_2.

Synthetic Rutile. In contrast to ilmenite, only a small number of rutile deposits can be mined economically, and the price of natural rutile is therefore high. Consequently, many different processes have been developed to remove the iron from ilmenite concentrates without changing the grain size of the mineral because this is highly suitable for the subsequent fluidized-bed chlorination process. All industrial processes involve reduction of Fe^{3+} with carbon or hydrogen, sometimes after preliminary activation of the ilmenite by oxidation. Depending on the reducing conditions, either Fe^{2+} is formed in an activated ilmenite lattice, or metallic iron is produced.

The activated Fe^{2+}-containing ilmenite can be treated with hydrochloric or dilute sulfuric acid (preferably under pressure), and a “synthetic rutile” with a TiO_2 content of 85 – 96 % is obtained [100]. The solutions containing iron(II) salts are concentrated and then thermally decomposed to form iron oxide and the free acid, which can be used again in the digestion process [101].

Metallic iron can be removed in various ways. The following processes are described in the patent literature:

1. Size reduction followed by physical processes such as magnetic separation of flotation.
2. Dissolution in iron(III) chloride solutions [102], the resulting iron(II) salt is oxidized with air to give iron oxide hydroxides and iron(III) salts.
3. Dissolution in acid.
4. Oxidation with air in the presence of electrolytes. Various iron oxide or iron oxide hydroxide phases are formed depending on the electrolyte used. Possible electrolytes include iron(II) chloride solutions [103], ammonium chloride [104], or ammonium carbonate – carbonic acid [105].
5. Oxidation with the iron(III) sulfate from ilmenite digestion (see Crystallization.) [106], followed by crystallization of the iron(II) sulfate.
6. Chlorination to form iron(III) chloride [107].
7. Reaction with carbon monoxide to form iron carbonyls [108] which can be decomposed to give high-purity iron.

Another possible method of increasing the TiO_2 content of ilmenite is by partial chlorination of the iron in the presence of carbon. This is operated on a large scale by several companies [109], [110]. The most important companies producing synthetic rutile are located in Australia (Renison Goldfields Consolidated Tiwest, Westralien Sands), United States (Kerr-McGee Synthetic Rutile), India (Kerala Minerals and Metals, DCW, Bene-Chlor Chemicals), and Malaysia (Hitox). In 1994 production of synthetic rutile was ca. 669 × 10^3 t of contained TiO_2.

2.1.3. ***Production***

Titanium dioxide pigments are produced by two different processes. The older *sulfate process* depends on the breakdown of the titanium-containing raw material ilmenite or titanium slag with concentrated sulfuric acid at 150 – 220 °C. Relatively pure TiO_2 dihydrate is precipitated by hydrolysis of the sulfate solution, which contains colored heavy metal sulfates, sometimes in high concentration. The impurities are largely removed in further purification stages. The hydrate is then calcined, ground, and further treated.

In the *chloride process,* the titanium-containing raw materials ilmenite, leucoxene, natural and synthetic rutile, titanium slag, and anatase are chlorinated at 700 – 1200 °C. Titanium tetrachloride is separated from other chlorides by distillation. Vanadium tetrachloride (VCl_4) and vanadium oxychloride ($VOCl_3$) must, however, first be reduced to solid chlorides. The $TiCl_4$ is burnt at temperatures of 900 – 1400 °C to form TiO_2. This extremely pure pigment undergoes further treatment depending on the type of application.

2.1.3.1. *Sulfate Method*

The sulfate method is summarized in Figure 15.

Figure 15. Production of TiO_2 by the sulfate process

Grinding. The titanium-bearing raw materials are dried to a moisture content of < 0.1 %. Drying is mainly intended to prevent heating and premature reaction on mixing with sulfuric acid. The raw materials are ground in ball mills to give a mean particle size of ca. 40 µm. The combination of grinding and drying shown in Figure 15 (a) is recommended. The small amount of metallic iron present in titanium slag is removed magnetically (c), which almost completely eliminates hydrogen evolution during subsequent digestion.

Digestion. *Batch digestion* is usually employed. The ground raw materials (ilmenite, titanium slag, or mixtures of the two) are mixed with 80 – 98 % H_2SO_4. The ratio of H_2SO_4 to raw material is chosen so that the weight ratio of free H_2SO_4 to TiO_2 in the suspension produced by the hydrolysis is between 1.8 and 2.2 (the so-called "acid number"). The reaction in the digestion vessel (f) is started by adding water, dilute sulfuric acid, oleum, or sometimes steam. The temperature initially increases to 50 – 70 °C due to the heat of hydration of the acid. The exothermic sulfate formation then increases the temperature to 170 – 220 °C. If dilute acid or sparingly soluble raw materials are used, external heating is required.

After the maximum temperature has been reached, the reaction mixture must be left to mature for 1 – 12 h, depending on the raw material, so that the titanium-containing components become as soluble as possible. Digestion can be accelerated by blowing air through the mass while the temperature is increasing, and also during the maturing period.

Several *continuous digestion processes* have been proposed [112]. A proven method is to continuously feed a mixture of ilmenite and water together with the acid into a double-paddle screw conveyor. After a relatively short dwell time (< 1 h), a crumbly cake is produced [113]. This process utilizes a more limited range of raw materials than the batch process because they need to be very reactive.

Dissolution and Reduction. The cake obtained by digestion is dissolved in cold water or in dilute acid recycled from the process. A low temperature must be maintained (< 85 °C) to avoid premature hydrolysis, especially with the product from ilmenite. Air is blown in to agitate the mixture during dissolution. With the ilmenite product, the TiO_2 concentration of the solution is 8 – 12 wt %, and with the slag product between 13 and 18 wt %.

The trivalent iron is hydrolyzed together with the titanium compounds, and adheres to the titanium oxide hydrate. Therefore, all the Fe^{3+} is reduced to Fe^{2+} by scrap iron during dissolution of the ilmenite product, or immediately afterwards. Reoxidation of the iron during subsequent processing is prevented with Ti^{3+} which is obtained by reducing a small part of the Ti^{4+}. Alternatively, reduction of Ti^{4+} to Ti^{3+} can be carried out in part of the solution under optimized conditions; this concentrated Ti^{3+} solution is then added in a controlled manner to the reaction solution [114]. In solutions obtained from titanium slag, the Ti^{3+} content of the solution must be decreased by oxidation with atmospheric oxygen so that no loss of yield occurs during hydrolysis.

With both ilmenite and titanium slag, mixed digestion can be carried out in which the Ti^{3+} content of the slag reduces all the Fe^{3+} to Fe^{2+}. The dissolved products obtained from the separate digestion of ilmenite and titanium slag can also be mixed [115], [116].

Clarification. All undissolved solid material must be removed as completely as possible from the solution. The most economical method is to employ preliminary settling in a thickener (g), followed by filtration of the sediment with a rotary vacuum filter (h). The filtrate and the supernatant from the thickener are passed through filter presses (i) to remove fines. Owing to the poor filtering properties of the solution, the rotary filter must be operated as a precoat filter. Preliminary separation in the thickener must be assisted by adding chemicals to promote sedimentation. Attempts to carry out the entire clarification process in a single stage using automated filter presses have been reported [117].

Crystallization. The solutions from slag digestion contain 5 – 6 wt % $FeSO_4$, and those from ilmenite digestion 16 – 20 wt % $FeSO_4$ after reduction of the Fe^{3+}. The solution is cooled under vacuum to crystallize out $FeSO_4 \cdot 7\ H_2O$ (j) and reduce the quantity of $FeSO_4$ discharged with the waste acid. The concentration of the TiO_2 in the solution is thereby increased by ca. 25 %. The salt is separated by filtration or centrifugation (k).

The iron sulfate is used in water purification, and as a raw material for the production of iron oxide pigments. Alternatively, it can be dehydrated and thermally decomposed to give iron(III) oxide and sulfur dioxide.

Hydrolysis. Titanium oxide hydrate is precipitated by hydrolysis at 94 – 110 °C. Other sulfuric-acid-soluble components of the raw material are precipitated simultaneously, mainly niobium as its oxide hydrate.

Hydrolysis is carried out in brick-lined, stirred tanks (n) into which steam is passed. The hydrolysate does not have any pigment properties, but these are strongly influenced by the particle size and degree of flocculation of the hydrolysate (mean particle size of hydrolysate is ca. 5 nm, and of TiO_2 pigments 200 – 300 nm).

The properties of the hydrolysate depend on several factors:

1. The hydrolysis of concentrated solutions of titanium sulfate (170 – 230 g TiO_2/L) proceeds very sluggishly and incompletely (even if boiled) unless suitable nuclei are added or formed to accelerate hydrolysis. The nuclei are usually produced by two methods. In the Mecklenburg method, colloidal titanium oxide hydrate is precipitated with sodium hydroxide at 100 °C; 1 % of this hydrate is sufficient. In the Blumenfeld method a small part of the sulfate solution is hydrolyzed in boiling water and then added to the bulk solution [118]. The particle size of the hydrolysate depends on the number of nuclei.
2. The particle size and degree of flocculation of the hydrolysate depend on the intensity of agitation during the nuclei formation by the Blumenfeld method and also during the initial stage of the hydrolysis.
3. The titanium sulfate concentration has a great influence on the flocculation of the hydrolysate. It is adjusted, if necessary by vacuum evaporation, to give a TiO_2 content of 170 – 230 g/L during hydrolysis. Lower concentrations result in a coarser particle size.
4. The acid number should be between 1.8 and 2.2. It has a considerable effect on the TiO_2 yield and on the particle size of the hydrolysate. For a normal hydrolysis period (3 – 6 h) the TiO_2 yield is 93 – 96 %.
5. The properties of the hydrolysate are affected by the concentrations of other salts present, especially $FeSO_4$. High concentrations lead to finely divided hydrolysates.
6. The temperature regime mainly affects the volume – time yield and hence the purity of the hydrolysate.

Purification of the Hydrolysate. After hydrolysis, the liquid phase of the titanium oxide hydrate suspension contains 20 – 28 % H_2SO_4 and various amounts of dissolved sulfates, depending on the raw material. The hydrate is filtered off from the solution (p_1) (weak acid), and washed with water or dilute acid. Even with acid washing, too many heavy metal ions are adsorbed on the hydrate for it to be directly usable in the production of white pigment. Most of the impurities can be removed by reduction (bleaching), whereby the filter cake is slurried with dilute acid (3 – 10 %) at 50 – 90 °C and mixed with zinc or aluminum powder (q). Bleaching can also be carried out with powerful nonmetallic reducing agents (e.g., $HOCH_2 – SO_2Na$). After a second filtration and washing process (p_2), the hydrate only has low concentrations (ppm) of colored impurities but still contains chemisorbed 5 – 10 % H_2SO_4. This cannot be removed by washing and is driven off by heating to a high temperature.

Doping of the Hydrate. When producing titanium dioxide of maximum purity, the hydrate is heated (calcined) without any further additions. This gives a fairly coarse grade of TiO_2 with a rutile content that depends on the heating temperature. However, to produce specific pigment grades, the hydrate must be treated with alkali-metal compounds and phosphoric acid as mineralizers (< 1 %) prior to calcination (r). Anatase pigments contain more phosphoric acid than rutile pigments. To produce rutile pigments, rutile nuclei (< 10 %) must be added; ZnO, Al_2O_3, and/or Sb_2O_3 (< 3 %) are sometimes also added to stabilize the crystal structure.

Nuclei are produced by converting the purified titanium oxide hydrate to sodium titanate, which is washed free of sulfate and then treated with hydrochloric acid to produce the rutile nuclei. Rutile nuclei can also be prepared by precipitation from titanium tetrachloride solutions with sodium hydroxide solution.

Calcination. The doped hydrate is filtered with rotary vacuum filters (s) to remove water until a TiO_2 content of ca. 30 – 40 % is reached. Pressure rotary filters or automatic filter presses can also be used to obtain a TiO_2 content of ca. 50 %. Some of the water-soluble dopants are lost in the filtrate and can be replaced by adding them to the filter cake before it is charged into the kiln. Calcination is performed in rotary kilns (t) directly heated with gas or oil in countercurrent flow. Approximately two-thirds of the residence time (7 – 20 h in total) is needed to dry the material. Above ca. 500 °C, sulfur trioxide is driven off which partially decomposes to sulfur dioxide and oxygen at higher temperatures. The product reaches a maximum temperature of 800 – 1100 °C depending on pigment type, throughput, and temperature profile of the kiln. Rutile content, particle size, size distribution, and aggregate formation are extremely dependent on the operating regime of the kiln. After leaving the kiln, the clinker can be indirectly cooled or directly air-cooled in drum coolers (u).

The exhaust gas must have a temperature of >300 °C at the exit of the kiln to prevent condensation of sulfuric acid in the ducting. Energy can be saved by recirculating some of the gas to the combustion chamber of the kiln and mixing it with the fuel gases as a partial replacement for air. Alternatively, it can be used for concentrating the dilute acid (see Section Problems with Aqueous and Gaseous Waste). The gas then goes to the waste-gas purification system.

Grinding. The agglomerates and aggregates in the clinker can be reduced to pigment fineness by wet or dry grinding. Coarse size reduction should be carried out in hammer mills prior to wet grinding in tube mills (with addition of wetting agents). The coarse fraction can be removed from the suspension by centrifugation, and recycled to the mills. Hammer mills, cross-beater mills, and particularly pendular and steam-jet mills are suitable for dry grinding. Special grinding additives can be used that act as wetting agents during subsequent pigment treatment or improve the dispersibility of untreated pigments.

2.1.3.2. *The Chloride Process*

The chloride process is summarized in Figure 16.

Figure 16. Flow diagram of TiO_2 production by the chloride process

Chlorination. The titanium in the raw material is converted to titanium tetrachloride in a reducing atmosphere. Calcined petroleum coke is used as the reducing agent because it has an extremely low ash content and, due to its low volatiles content, very little HCl is formed. The titanium dioxide reacts exothermically as follows:

$$TiO_2 + 2\,Cl_2 + C \rightarrow TiCl_4 + CO_2$$

As the temperature rises, an endothermic reaction also occurs to an increasing extent in which carbon monoxide is formed from the carbon dioxide and carbon. Therefore, oxygen must be blown in with the chlorine to maintain the reaction temperature between 800 and 1200 °C. The coke consumption per tonne of TiO_2 is 250 – 300 kg. If CO_2-containing chlorine from the combustion of $TiCl_4$ is used, the coke consumption increases to 350 – 450 kg.

The older *fixed-bed chlorination method* is hardly used today. In this process, the ground titanium-containing raw material is mixed with petroleum coke and a binder, and formed into briquettes. Chlorination is carried out at 700 – 900 °C in brick-lined reactors.

Fluidized-bed chlorination was started in 1950. The titanium raw material (with a particle size similar to that of sand) and petroleum coke (with a mean particle size ca. five times that of the TiO_2) are reacted with chlorine and oxygen in a brick-lined fluidized-bed reactor (Fig. 16, c) at 800 – 1200 °C. The raw materials must be as dry as possible to avoid HCl formation. Since the only losses are those due to dust entrainment the chlorine is 98 – 100 % reacted, and the titanium in the raw material is 95 – 100 % reacted, depending on the reactor design and the gas velocity. Magnesium chloride and calcium chloride can accumulate in the fluidized-bed reactor due to their low volatility. Zirconium silicate also accumulates because it is chlorinated only very slowly at the temperatures used. All the other constituents of the raw materials are volatilized as chlorides in the reaction gases.

The ceramic cladding of the fluidized-bed reactor is rather rapidly destroyed by abrasion and corrosion. If chlorination is interrupted, there is a further danger that the raw materials may sinter and eventually cannot be fluidized.

Gas Cooling. The reaction gases are cooled with liquid $TiCl_4$ either indirectly or directly (d). Crystallization of the chlorides of the other components causes problems because they tend to build up on the cooling surfaces, especially the large quantities of iron(II) and iron(III) chlorides formed on chlorination of ilmenite [119]. In this first stage, the reaction gases are cooled only down to a temperature (< 300 °C) at which the accompanying chlorides can be satisfactorily separated from the $TiCl_4$ by condensation or sublimation (e).

The gas then consists mainly of $TiCl_4$, and is cooled below 0 °C, causing most of the $TiCl_4$ to condense (f). The small amounts of $TiCl_4$ and Cl_2 remaining in the exhaust gas (CO_2, CO, and N_2) are removed by scrubbing with alkali (t).

Purification of $TiCl_4$. The chlorides that are solid at room temperature and the entrained dust can be separated from the $TiCl_4$ by simply evaporating (distilling) this off (j). Dissolved chlorine can be removed by heating or reduction with metal powders (Fe, Cu, or Sn).

Removal of vanadium tetrachloride (VCl_4) and vanadium oxychloride ($VOCl_3$) from the $TiCl_4$ by distillation is very difficult owing to the closeness of their boiling points. They are therefore reduced to form solid, low-value vanadium chlorides (i). An enormous number of reducing agents have been recommended; important examples are copper, titanium trichloride, hydrogen sulfide, hydrocarbons, soaps, fatty acids, and amines. After subsequent evaporation (j) the titanium chloride should contain < 5 ppm vanadium. If organic reducing agents are used, the residues may cause problems by baking onto the surfaces of the heat exchanger.

Phosgene and $SiCl_4$ can be removed by fractional distillation.

Combustion of $TiCl_4$ and Recovery of TiO_2. Titanium tetrachloride is combusted with oxygen at 900 – 1400 °C to form TiO_2 pigment and chlorine (n). The purified $TiCl_4$ is vaporized (k) and the vapor is indirectly heated to ca. 500 – 1000 °C (l). The reaction

$$TiCl_4 + O_2 \rightarrow 2\,Cl_2 + TiO_2$$

is weakly exothermic, and requires a high reaction temperature, so that the oxygen must also be heated to>1000 °C (m). This can be achieved with an electric plasma flame, by reacting part of the oxygen with carbon monoxide, or by indirect heating. Hot $TiCl_4$ and oxygen (110 – 150 % of the stoichiometric amount) are fed separately into a reaction chamber where they must be mixed as rapidly and completely as possible to give a high reaction rate. For this reason, and also because the TiO_2 has a strong tendency to cake onto the walls [120-122], many different reactor designs have been proposed and used. The same considerations apply to the cooling unit (o) where the pigment is very rapidly cooled to below 600 °C. Cooling zones of various geometries are used. If caking occurs, the material can be removed by introducing abrasive particles [123], [124].

The mixture of gases (Cl_2, O_2, CO_2) and pigment can be further cooled during dry separation of the pigment either indirectly or directly by solid particles, e.g., sand. The pigment-containing gas is then filtered (p). The gas stream is recycled to the cooling zone (o) of the combustion furnace and to the chlorination process as oxygen-containing chlorine via the liquefaction unit (u). The chlorine adsorbed on the pigment can be removed by heating or by flushing with nitrogen or air.

The wet separation process, in which the pigment-containing gas mixture (Cl_2, O_2, and CO_2) is quenched in water, has not become established.

2.1.3.3. *Pigment Quality*

The quality of the TiO_2 pigment is influenced by various factors. Reaction temperature, excess oxygen, and flow conditions in the reactor affect particle size and size distribution. Therefore, optimum conditions must be established for every reactor design. Caking of the TiO_2 on the walls of the reactor leads to impairment of quality.

The presence of water and a cesium compound during combustion of the $TiCl_4$ gives rise to nuclei which promote the formation of finely divided pigment particles with high scattering power [125]. It can be added directly to the oxygen or can be produced by the combustion of hydrogen-containing materials.

The presence of $AlCl_3$ promotes the formation of rutile and a more finely divided pigment. It is added in amounts of up to 5 mol %. Many methods have been proposed for rapidly generating and directly introducing the $AlCl_3$ vapor into the $TiCl_4$ vapor. Addition of PCl_3 and $SiCl_4$ suppresses rutile formation, so that anatase pigment is obtained [126]. However, pigments of this type have not appeared on the market.

Pigments produced by the chloride process (chloride pigments) have better lightness and a more neutral hue than pigments produced by the sulfate process (sulfate pigments). Pigments used in demanding applications are almost always subjected to inorganic aftertreatment.

2.1.3.4. *Aftertreatment*

Aftertreatment of the pigment particles improves the weather resistance and lightfastness of the pigmented organic matrix, and dispersibility in this matrix. The treatment consists of coating the individual pigment particles with colorless inorganic compounds of low solubility by precipitating them onto the surface. However, this reduces the optical performance of the pigment approximately in proportion to the decrease in the TiO_2 content. The surface coatings prevent direct contact between the binder matrix and the reactive surface of the TiO_2. The effectiveness of these coatings largely depends on their composition and method of application, which may give too porous or too dense a coating. The treatment process also affects the dispersibility of the pigment, and therefore a compromise often has to be made. High weather resistance and good dispersibility of the pigment in the binder or matrix are usually desired. These effects are controlled by using different coating densities and porosities. Other organic substances can be added during the final milling of the dried pigment.

Several types of treatment are used:

1. Deposition from the gas phase by hydrolysis or decomposition of volatile substances such as chlorides or organometallic compounds. Precipitation onto the pigment surface is brought about by adding water vapor. This method is especially applicable to chloride pigments, which are formed under dry conditions.
2. Addition of oxides, hydroxides, or substances that can be adsorbed onto the surface during pigment grinding. This can produce partial coating of the pigment surface.

3. Precipitation of the coating from aqueous solutions onto the suspended TiO_2 particles. Batch processes in stirred tanks are preferred; various compounds are deposited one after the other under optimum conditions. There is a very extensive patent literature on this subject. Continuous precipitation is sometimes used in mixing lines or cascades of stirred tanks. Coatings of widely differing compounds are produced in a variety of sequences. The most common are oxides, oxide hydrates, silicates, and/or phosphates of titanium, zirconium, silicon, and aluminum. For special applications, boron, tin, zinc, cerium, manganese, antimony, or vanadium compounds can be used [127], [128].

Three groups of pigments have very good lightfastness or weather resistance:

1. Pigments with dense surface coatings for paints or plastics formed by:
   a. Homogeneous precipitation of SiO_2 with precise control of temperature, pH, and precipitation rate [129]: ca. 88 % TiO_2
   b. Two complete aftertreatments, calcination is performed at 500 – 800 °C after the first or second aftertreatment [130]: ca. 91 % TiO_2
   c. Aftertreatment with Zr, Ti, Al, and Si compounds, sometimes followed by calcination at 700 – 800 °C [131]: ca. 95 % TiO_2
2. Pigments with porous coatings for use in emulsion paints obtained by simple treatment with Ti, Al, and Si compounds, giving a silica content of 10 % and a TiO_2 content of 80 – 85 %
3. Lightfast pigments with dense surface coatings for the paper industry that have a stabilized lattice and a surface coating based on silicates or phosphates of titanium, zirconium, and aluminum: ca. 90 % TiO_2

Coprecipitation of special cations such as antimony or cerium can improve lightfastness further [132]. After treatment in aqueous media, the pigments are washed on a rotary vacuum filter or filter press until they are free of salt, and then dried in, e.g., belt, spray, or fluidized-bed dryers.

Before micronizing the pigment in air-jet or steam-jet mills, and sometimes also before drying, the pigment surface is improved by adding substances to improve dispersibility and facilitate further processing. The choice of compounds used, which are mostly organic, depends on the intended use of the pigment. The final surface can be made either hydrophobic (e.g., using silicones, organophosphates, and alkyl phthalates) or hydrophilic (e.g., using alcohols, esters, ethers and their polymers, amines, organic acids). Combinations of hydrophobic and hydrophilic substances have proved especially useful for obtaining surface properties that give better dispersibility and longer shelf life [133].

2.1.3.5. *Problems with Aqueous and Gaseous Waste*

Aqueous Waste. In the *sulfate process*, 2.4 – 3.5 t concentrated H_2SO_4 are used per tonne of TiO_2 produced, depending on the raw material. During processing, some of this sulfuric acid is converted to sulfate, primarily iron(II) sulfate, the rest is obtained as free sulfuric acid (weak acid). Filtration of the hydrolysate suspension can be carried out to give 70 – 95 wt % of the SO_4^{2-} in a weak acid fraction containing ca. 20 – 25 % free acid, the remaining sulfate (5 – 30 %) is highly diluted with wash-water.

In the past it was common practice to discharge acid directly into the open sea or coastal waters. For a long time the weak-acid problem was the subject of controversy. As a result the European Community decided to stop the discharge of weak acid into open waters by 1993.

The European TiO_2 producers developed various effluent-treatment processes to meet the environmental requirements [134]. The most important processes are the precipitation of gypsum from the weak acid [135] and the concentration and recovery of the free and bound acid.

In the gypsum process, the acid effluent is treated in a first stage with finely divided $CaCO_3$ to precipitate white gypsum. After filtering off, washing, and drying, the white gypsum is used for the manufacturing of plasterboard. In a second stage, the residual metal sulfates in the filtrate are precipitated as metal hydroxides and further gypsum by adding calcium hydroxide. This mixture, the so-called red gypsum, can be used for landfill.

In the recycling process, both the free and the bound sulfuric acid (as metal sulfates) can be recovered from the weak acid in the calcination furnace (k, Fig. 17) and in metal sulfate calcination (Fig. 18). The process consists of two stages:

1. Concentration and recovery of the free acid by evaporation
2. Thermal decomposition of the metal sulfates and production of sulfuric acid from the resulting sulfur dioxide

Figure 17. Weak acid recovery plant used by Sachtleben Chemie (based on know-how of Bayer AG)

Figure 18. Waste heat recovery and sulfuric acid recycling during weak acid treatment (Bayer AG)

As a result of energy requirements only acid containing > 20 % H_2SO_4 can be economically recovered by evaporation. The weak acid is concentrated from ca. 20 – 25 % to ca. 28 % with minimum heat (i.e., energy) consumption, e.g., by using waste heat from sulfuric acid produced by the contact process [136], or from the waste gases from the calcination kilns used in TiO_2 production [137] (Fig. 18).

Following preliminary evaporation, further concentration is carried out in multi-effect vacuum evaporators. Since the water vapor pressure decreases strongly as the H_2SO_4 concentration increases, in general only two-stage evaporation can effectively exploit the water vapor as a heating medium. Evaporation produces a suspension of metal sulfates in 60 – 70 % sulfuric acid (stage 1 in Fig. 17). The suspension is cooled to 40 – 60 °C in a series of stirred tanks (stage 2, d) [138], giving a product with good filtering properties and an acid of suitable quality for recycling to the digestion process. Filtration (stage 3, e) is usually carried out with pressure filters [139] because they give a filter cake with an extremely low residual liquid content.

The concentration of the acid recycled to the digestion process depends on the quality of the titanium-containing raw material. For raw materials with a high titanium content, the 65 – 70 % sulfuric acid separated from the metal sulfates must be further concentrated to give 80 – 87 % acid (stage 5).

Concentration can be carried out in steam-heated vacuum evaporators, or by using the heat from the TiO_2 calcination kilns [140]. Cooling the acid obtained after this concentration process yields a suspension of metal sulfates that can be directly used for digestion of the raw material. The metal sulfates recovered from the sulfuric acid in stage 3 are moist because they contain 65 – 70 % sulfuric acid; they therefore have no direct use. They can be converted to a disposable material by reaction with calcium compounds [141]. Thermal decomposition of the metal sulfates to form the metal oxides, sulfur dioxide, water, and oxygen is energy intensive, but is advantageous from the ecological point of view. The energy requirement is ca. 4×10^9 J per tonne of filter cake. Thermal decomposition is carried out at 850 – 1100 °C in a fluidized-bed furnace (stage 6). The energy is supplied by coal, pyrites, or sulfur. The sulfur dioxide produced by the thermal decomposition is purified by the usual methods, dried, and converted into sulfuric acid or oleum. This pure acid or oleum is mixed with the recovered sulfuric acid and used in the digestion process.

The metal oxides produced by thermal decomposition contain all the elements initially present in the raw material apart from the titanium which has been converted into pigment. The mixture of metal oxides, mainly iron oxide, can be used as an additive in the building materials industry.

The continually increasing demand for environmentally friendly industrial processes has also led to the development of techniques for recycling the 5 – 30 % sulfate remaining in the the acidic wash water. [143]. In modern processes, up to 99 % of the sulfuric acid can be recovered and reused in production. In the *chloride process*, wastewater problems arise if the raw material contains < 90 % TiO_2. The metal chloride byproducts are sometimes disposed of in solution by the “deep well” method (e.g., at Du Pont). The metal chloride solutions are pumped via deep boreholes into porous geological strata. Special geological formations are necessary to avoid contamination of the groundwater by impurities.

Increasing restrictions also apply to the chloride process, so that efforts are continually being made to use the iron chloride byproduct, e.g., in water treatment and as a

flocculation agent. [144]. A process for treating metal chlorides with cement and alkaline compounds to produce rocklike aggregates for road building is described in [145].

Waste Gas Problems. The gases produced in the calcination kiln are cooled in a heat exchanger, and entrained pigment is removed, washed, and recycled to the process. The SO_2 and SO_3 formed during calcination are then scrubbed from the gases to form dilute sulfuric acid which is recycled.

2.1.4. *Economic Aspects*

The burning of $TiCl_4$ with oxygen or the calcination of TiO_2 hydrolysates produces either anatase or rutile pigments, depending on the doping and lattice stabilization. They are marketed directly or after being coated with oxides or hydroxides of various elements. Different treatments are necessary depending on the field of application, and all major pigment producers have a large number of pigment grades. Product groups are listed in Table 15. Pigments of all grades are available with or without organic treatment. Over 400 different TiO_2 pigment grades are on the market. Table 16 gives the capacities and processes of the most important pigment producers.

Table 15. Classification of TiO_2 pigments according to composition (DIN E 55 912, sheet 1, issue 07.85; ISO 591, 1977)

Pigment	Class	TiO_2 (min.), wt %	Water-soluble salts, wt %	Volatiles (max.), wt %
Anatase (Type A)	A 1	98	0.6	0.5
	A 2	92	0.5	0.8
Rutile (Type R)	R 1	97	0.6	0.5
	R 2	90	0.5	1.5
	R 3	80	*	*

* To be agreed.

Total, Far East (excluding Japan)					*246*
Total world capacity			*2080*	*1828*	*3908*

A considerable increase of capacity is planned by debottlenecking and building new plants. Pigment plant capacity is forecast to grow to 5.2×10^6 t in 2005 [146].

Powdered TiO_2 pigments are usually supplied in 25 kg sacks (50 lbs, USA) or in big bags containing 0.5 – 1 t pigment. Aqueous suspensions with solids contents of 68 – 75 % are also available and have great advantages as regards the distribution and metering of the pigment in aqueous systems. The dust formation that occurs with dry pigment is also avoided. With the development of products with improved flow properties and modern pneumatic delivery technology, supply in silo wagons is becoming increasingly important.

2.1.5. *Pigment Properties*

The pigment properties are extremely important when TiO_2 is used as a white pigment; they include lightening power, hiding power, lightness, hue, gloss formation, gloss haze, dispersibility, lightfastness, and weather resistance. These properties are a function of chemical purity, lattice stabilization, particle size and size distribution, and the coating produced by aftertreatment. They also depend on the medium and cannot generally be accurately described in scientific terms. Some of the important properties of TiO_2 pigments are described below.

Scattering Power. The refractive indices of rutile and anatase are very high (2.70 and 2.55, respectively). Even after incorporation in a wide range of binders, they lie in the range between 1.33 (water) and 1.73 (polyester fibers). The scattering power depends on the particle size, and for TiO_2 is at its maximum at a particle size of 0.2 µm (Mie's theory) [28]. The scattering power also depends on the wavelength; TiO_2 pigment particles with a size ≤0.2 µm scatter light of shorter wavelengths more strongly and therefore show a slight blue tinge, while larger particles have a yellow tone.

Hue. The whiteness (lightness and hue) of TiO_2 pigments depends primarily on the crystalline modification, the purity, and the particle size of the TiO_2 (see above). As the absorption band (385 nm) of anatase pigments is shifted into the UV region, compared with rutile pigments they have less yellow undertone. Any transition elements present in the crystal structure have an adverse effect on the whiteness, so manufacturing conditions are of the greatest importance. Thus, pigments produced by the chloride process (which includes distillative purification of $TiCl_4$ before the combustion stage) have a higher color purity and very high lightness values.

Dispersion. Good disintegration and dispersion of the TiO_2 pigments in the medium are necessary to obtain high gloss and low gloss haze. These requirements are satisfied by intensive grinding and by coating the pigment surface with organic compounds. The compounds used for this surface treatment depend on the field of application (see Section Aftertreatment).

Lightfastness and Weather Resistance. Weathering of paints and coatings containing TiO_2 leads to pigment chalking [147]. If weathering occurs in the absence of oxygen, or in binders with low permeability to oxygen (e.g., in melamine – formaldehyde resins), no chalking is observed, but graying takes place, which decreases on exposure to air. Graying is greatly reduced in the absence of water. Both effects are more severe with anatase pigments. Empirical stabilization processes have been developed by pigment producers, e.g., doping with zinc or aluminum prior to calcination.

According to modern theories, impairment of the lightfastness and weather resistance of TiO_2 pigments proceeds according to the following cycle [148]:

1. Molecules of water are bound to the TiO_2 surface, forming hydroxyl groups on the surface.
2. Absorption of light of short wavelength (anatase < 385 nm, rutile < 415 nm) occurs, producing an electron and an electron defect or “hole” (exciton) in the crystal lattice which migrate to the surface of the pigment.
3. At the surface of the pigment, an OH^- ion is oxidized to an $OH^\cdot$ radical by an electron “hole”. The OH^- ion is then desorbed and can oxidatively break down the binder. A Ti^{3+} ion is simultaneously produced by reduction of Ti^{4+} with the remaining electron of the exciton.
4. The Ti^{3+} ion can be oxidized by adsorbed oxygen with formation of an O_2^- ion. The latter reacts with H^+ and is converted into an $HO_2^\cdot$ radical.
5. The cycle ends with the binding of water to the regenerated TiO_2 surface.

The chalking process can be regarded as the reaction of water and oxygen to form $OH^\cdot$ and $HO_2^\cdot$ radicals under the influence of shortwave radiation and the catalytic activity of the TiO_2 surface:

$$H_2O + O_2 \xrightarrow[TiO_2]{h\nu} OH^\cdot + HO_2^\cdot$$

The enthalpy requirement for this reaction (312 kJ/mol) is provided by radiation of wavelength 385 nm. The cycle (1) – (5) is broken by excluding air or water. If oxygen is excluded or a binder is chosen in which the diffusion of oxygen is rate determining, a concentration of Ti^{3+} ions builds up. Graying then takes place, but this decreases with gradual exposure to oxygen. If water is excluded, rehydration and formation of surface hydroxyl groups do not take place; breakdown of the binder therefore ceases. Despite this photochemical breakdown of the binder, treated rutile pigments are used to stabilize many binders. This is because nonpigmented coatings are degraded by exposure to light and weathering; the added TiO_2 pigments prevent light from penetrating the deeper layers of the coating film and thus inhibit breakdown of the binder. High-quality TiO_2 pigments must satisfy stringent requirements with respect to weather resistance. They must withstand the severe climatic conditions of the Florida test, resisting a two-year exposure without appreciable chalking or deterioration of gloss.

2.1.6. *Analysis*

The crystal structure of the pigments is determined by X-ray analysis which is sensitive enough to determine 0.3 – 0.5 % anatase in the presence of 99.7 – 99.5 % rutile. For standards, see Table 1 (Titanium dioxide pigments; “Methods of analysis” and “Specification”).

A qualitative test for TiO_2 is a blue – violet coloration of beads of microcosmic salt ($NaNH_4HPO_4 \cdot 4\ H_2O$), or a yellow – orange coloration produced when hydrogen peroxide is added to a test solution in hot, concentrated sulfuric acid containing ammonium sulfate. For quantitative determination, the pigment is dissolved or digested in sulfuric acid and the solution is reduced to Ti^{3+} with cadmium, zinc, or aluminum. The Ti^{3+} ions are then usually titrated with a standard solution of iron(III) ammonium sulfate solution, with potassium rhodanide as an indicator, or using potentiometric end point determination.

Impurities can be determined by wet analysis, X-ray fluorescence, or spectrographic analysis (e.g., atomic absorption).

Typical analysis figures for an untreated rutile pigment are TiO_2 99.4 %, K_2O 0.24 %, P_2O_5 0.21 %, Fe_2O_3 40 ppm, Sb_2O_3 24 ppm, Al_2O_3 20 ppm, Mg 5 ppm, Zn 3 ppm, Cr 2 ppm, Mn, Cu, Hg, Cd, Co, Ni, Se, Sn, Ag < 1 ppm.

2.1.7. *Uses of Pigmentary TiO_2*

Titanium dioxide is used universally, having almost completely replaced other white pigments. Consumption figures for 1996 are given in Table 17 [149]. The greatest annual increase in use has been for coloring plastics (> 5.5 %), followed by the coloring of paper (ca. 3.0 %). Geographically, the increase in consumption of TiO_2 has been the greatest in Asia (see Table 18).

Table 17. World consumption of TiO_2 pigments in 1996 [149]

Use	Consumption, 10^3 t	Percentage

Coatings	1988	59
Paper	424	13
Plastics	686	20
Others	286	8
Total	3384	100

Table 18. Predicted percentage annual growth rates for use of TiO_2 (1993 – 2000) [149]

End use	United States	Middle and Eastern Europe, Africa	Asia and Pacific	World total
Coatings	3.4	2.0	5.0	2.5
Paper	2.0	4.0	4.0	3.0
Plastics	4.5	5.0	10.0	5.5
Total	3.0	2.5	6.5	3.3

Paints and coatings amount for the largest volume of TiO_2 production. The presence of the pigment enables the protective potential of the coating material to be fully exploited. As a result of continuing developments in TiO_2 pigments, coatings only a few micrometers thick fully cover the substrate. Commercially available pigments permit paint manufacture with simple dispersion equipment, such as disk dissolvers. Organic treatment (see Section Aftertreatment) prior to steam jet micronization yields pigments with improved gloss properties and reduced gloss haze for use in stoving enamels. Sedimentation does not occur when these products are stored, and they possess good lightfastness and weather resistance.

Printing Inks. Modern printing processes operate at coating thicknesses of < 10 µm, and therefore require the finest possible TiO_2 pigments. These very low film thicknesses are only possible with TiO_2 pigments that have a lightening (reducing) power seven times that of lithopone. Because of its neutral hue, TiO_2 is especially suitable for lightening (reducing) colored pigments.

Plastics. Titanium dioxide is used to color durable and nondurable goods such as toys, appliances, automobiles, furniture, and plastic packaging films. Furthermore, TiO_2 pigments absorb UV radiation with a wavelength < 415 nm and thus protect the pigmented goods from these harmful rays.

Fibers. Titanium dioxide pigments give a matt appearance to synthetic fibers, eliminating the greasy appearance caused by their translucent properties. Anatase pigments are used for this because their abrasive effect on the spinning operation is about one quarter that of the rutile pigments. The poor lightfastness of anatase pigments in polyamide fibers can be improved by treatment with manganese or vanadium phosphate.

Paper. In Europe, fillers such as kaolin, chalk, or talc are preferred as brightening agents and opacifiers in paper manufacture. Titanium dioxide pigments are suitable for very white paper that has to be opaque even when very thin (air mail or thin printing paper). The TiO_2 can be incorporated into the body of the paper or applied as a coating to give a superior quality ("art" paper).

Laminated papers are usually colored with extremely lightfast rutile pigments before being impregnated with melamine – urea resin for use as decorative layers or films.

Other areas of application for TiO_2 pigments include the enamel and ceramic industries, the manufacture of white cement, and the coloring of rubber and linoleum.

Titanium dioxide pigments are also used as UV absorbers in sunscreen products, soaps, cosmetic powders, creams, toothpaste, cigar wrappers, and in the cosmetics industry. Their most important properties are their lack of toxicity, compatibility with skin and mucous membranes, and good dispersibility in organic and inorganic solutions and binders.

Electrically conducting TiO_2 pigments have been produced by an aftertreatment to give a coating of mixed oxides of indium and tin, or antimony and tin [150]. These pigments are applied to fibers used in photosensitive papers for electrophotography, and for the production of antistatic plastics.

2.1.8. *Uses of Nonpigmentary TiO_2*

A number of industrial products require TiO_2 starting materials with well-defined properties for a specific application. Some of the most important of these grades of titanium dioxide are those with a high specific surface area, a small particle size, and very high reactivity. Stringent requirements often exist regarding purity and property consistency. The most important applications for nonpigmentary TiO_2 are vitreous enamels, glass and glass ceramics, electroceramics, catalysts and catalyst supports, welding fluxes, colored pigments, electrical conductors, chemical intermediates (e.g., potassium fluorotitanate), structural ceramics, UV absorbers, and refractory coatings.

Electroceramics. Titanates, for example, barium, strontium, calcium, and lead titanate, prepared from finely divided, high-purity TiO_2 hydrolysates, are used in capacitors, PTC resistors, and piezoelectric materials. The specifications of the TiO_2 starting materials with respect to purity, reactivity, and sintering properties are expected to become more stringent. The market is estimated to be several thousands of tonnes per annum as TiO_2. Strong annual growth is expected.

Catalysts. The most important application for TiO_2 is the removal of nitrogen oxides from waste gases from power stations and industry. The nitrogen oxides in the waste gas react with ammonia in the presence of oxygen over the catalyst to produce nitrogen and water (SCR, Selective Catalytic Reduction) [153]. The world market for SCR catalysts is believed to be several thousand tonnes per annum as TiO_2. In addition to TiO_2 the catalysts usually contain ca. 10 wt % tungsten oxide and 1 wt % V_2O_5 and are extruded into a honeycomb shape or supported in thin layers on metal sheets. The TiO_2 has high specifications with respect to purity, particle size, and porosity to ensure that the desired catalytic activity is obtained. An increasing demand is expected for the removal of nitrogen oxides from waste gases from stationary and nonstationary diesel engines. Another application is the combined removal of nitrogen oxides and dioxins from the waste gases of refuse incinerators [154].

Mixed Metal Oxide Pigments. The starting material is a TiO_2 hydrolysate, which is calcined with oxides of transition metals to form chromium rutile or nickel rutile pigments (see Section Properties). Depending on the particle size, pigments with various shades of yellow are produced. These pigments should have considerable growth potential on account of their quality and environmental safety.

UV Absorption. Nanostructured TiO_2 particles (particle size 5 – 50 nm) are used as sunscreens in the cosmetic industry. Nanosized TiO_2 is an effective absorber of UV-B (280 – 320 nm) and UV-A radiation (320 – 400 nm). Because of its small particle size, it appears transparent [155]. Intensive research work is in progress worldwide aimed at utilizing the photoactivity of TiO_2. Titanium dioxide catalyzes the decomposition of organic compounds in wastewater [156]; water is decomposed into hydrogen and oxygen in the presence of sunlight.

2.1.9. *Toxicology*

Titanium dioxide is highly stable and is regarded as completely nontoxic. Investigations on animals which have been fed TiO_2 over a long period give no indication of titanium uptake [157]. Absorption of finely divided TiO_2 pigments in the lungs does not have any carcinogenic effect [158].

2.2. Zinc Sulfide Pigments [159-161]

White pigments based on zinc sulfide were first developed and patented in 1850 in France. Although they are still of economic importance, they have continually lost market volume since the early 1950s when titanium dioxide was introduced. Only one modern production installation for zinc sulfide pigments still exists in the market-economy-oriented industrial nations (Sachtleben Chemie, Germany). There are other production plants in eastern Europe and in China.

The zinc-sulfide-containing white pigment with the largest sales volume is *lithopone* [1345-05-7], which is produced by coprecipitation and subsequent calcination of a mixture of zinc sulfide [1314-98-3], ZnS, M_r 97.43, and barium sulfate [7727-43-7], $BaSO_4$, M_r 233.40. For standards, see Table 1 (Lithopone pigments; "Specification"). Pure zinc sulfide is marketed as *Sachtolith.*

White zinc sulfide pigments maintain their market position in areas of use where not only their good light scattering ability but other properties such as low abrasion, low oil number, and low Mohs hardness are required.

They are often produced from many types of industrial waste. This recycling relieves pressure on the environment, as these materials would otherwise have to be disposed of.

2.2.1. *Properties*

Some physical and chemical properties of ZnS and $BaSO_4$ are given in Table 19.

Table 19. Properties of the components of zinc sulfide pigments

Property	Zinc sulfide	Barium sulfate *
Physical properties		
Refractive index *n*	2.37	1.64
Density, g/cm^3	4.08	4.48
Mohs hardness	3	3.5
Solubility in water (18 °C), wt %	1.8×10^{-4}	2.5×10^{-4}
Chemical properties		
Resistance to acids/bases	soluble in strong acids	insoluble
Resistance to organic solvents	insoluble	insoluble

* Component of lithopone.

A white pigment must not absorb light in the visible region (wavelength 400 – 800 nm), but should disperse incident radiation in this region as completely as possible. The spectral reflectance curves of zinc sulfide and barium sulfate (Fig. 19) fulfil these conditions to a large extent. The absorption maximum for ZnS at ca. 700 nm is a result of lattice stabilization with cobalt ions, whose function is explained in Section Lithopone.. The absorption edge in the UV-A region is responsible for the bluish-white tinge of zinc sulfide. Depending on the production process, zinc sulfide has a sphalerite or wurtzite lattice type.

Figure 19. Spectral reflectance curves of barium sulfate and zinc sulfide

a) Barium sulfate; b) Zinc sulfide (Co-doped)

The refractive index *n* of ZnS, which determines its scattering properties, is 2.37 and is much greater than that of plastics and binders (*n* = 1.5 – 1.6). Spheroidal ZnS particles have their maximum scattering power at a diameter of 294 nm. Barium sulfate does not directly contribute to the light scattering due to its relatively low refractive index (*n* = 1.64), but acts as an extender, and increases the scattering efficiency of the ZnS.

The barium sulfate in lithopone can be identified thermoanalytically by a reversible endothermic transformation at 1150 °C. Both Sachtolith and lithopone are thermally stable up to ca. 550 °C in the presence of air. Due to their low Mohs hardness, they are less abrasive than other white pigments. Barium sulfate is practically inert toward acids, bases, and organic solvents. Zinc sulfide is stable in aqueous media between pH 4 and 10, and is largely inert toward organic media. In the presence of water and oxygen, it can be oxidatively decomposed by the action of UV radiation.

2.2.2. *Production*

Raw Materials. The source of zinc can be zinc oxide from a smelter, zinc dross or sweepings, ammonium chloride slag from hot dip galvanizing, or liquid waste such as pickle liquors from galvanizing plants. Variations in the price of zinc have a large effect on the economics of zinc sulfide pigments.

The starting material for water-soluble barium compounds is fused barium sulfide produced by coke reduction of naturally occurring barite with a low silica and strontium content. Suitable barite is readily available from many deposits worldwide.

Lithopone. The reaction of equimolar quantities of $ZnSO_4$ and BaS produces a white, water-insoluble coprecipitate with the theoretical composition 29.4 wt % ZnS and 70.6 wt % $BaSO_4$:

$$ZnSO_4 + BaS \rightarrow ZnS + BaSO_4 \quad (1)$$

By using a different molar ratio, this composition can be changed; for example, precipitation according to Equation (2) gives a product containing 62.5 wt % ZnS and 37.5 wt % $BaSO_4$:

$$ZnSO_4 + 3\,ZnCl_2 + 4\,BaS \rightarrow 4\,ZnS + BaSO_4 + 3\,BaCl_2 \quad (2)$$

Figure 20 is a flow diagram of lithopone production. The *solutions of zinc salts* contain impurities (e.g., salts of iron, nickel, chromium, manganese, silver, cadmium) that depend on their origins. The main sources of zinc sulfate solutions are zinc electrolyses and the reprocessing of zinc scrap and zinc oxide. The first stage of purification consists of chlorination. Iron and manganese are precipitated as oxide-hydroxides, and cobalt, nickel, and cadmium as hydroxides. The solutions are then mixed with zinc dust at 80 °C. All the elements more noble than zinc (cadmium, indium, thallium, nickel, cobalt, lead, iron, copper, and silver) are almost completely precipitated, while zinc goes into solution. The metal slime is filtered off and taken to copper smelters for recovery of the noble metal components. A small quantity of a water-soluble cobalt salt is added to the purified zinc salt solution. The cobalt (0.02 – 0.5 %) becomes incorporated into the ZnS lattice during subsequent calcination to stabilize the final product against light. Zinc sulfide that is not treated in this way becomes gray in sunlight.

Figure 20. Flow diagram for lithopone production

a) Precipitation vessel; b) Rotary filter; c) Turbo dryer; d) Rotary kiln; e) Chilling vessel; f) Rake classifier; g) Thickener; h) Grinder; i) Silo

The *barium sulfide solution* is produced by dissolving fused barium sulfide in water. The barium sulfide is obtained by reducing an intimate mixture of crushed barite (ca. 1 cm lumps) with petroleum coke according to Equation (3) in a directly heated rotary kiln at 1200 – 1300 °C:

$$BaSO_4 + 2\,C \rightarrow BaS + 2\,CO_2 \quad (3)$$

The warm solution (60 °C) containing ca. 200 g/L barium sulfide is filtered and immediately pumped to the precipitation stage. Further purification is not necessary. Unreacted gangue and heavy metals are collected as insoluble sulfides in the filter cake. The almost clear solution can be stored only for a short period. Longer storage leads to undesirable polysulfide formation.

The zinc salt and BaS solutions are mixed thoroughly under controlled conditions (vessel geometry, temperature, pH, salt concentration, and stirring speed, see (a) in Fig. 20). The precipitated “raw lithopone” does not possess pigment properties. It is filtered off (b_1) and dried (c); ca. 2 cm lumps of the material are calcined in a rotary kiln (d) directly heated with natural gas at 650 – 700 °C. Crystal growth is controlled by adding 1 – 2 wt % NaCl, 2 wt % Na_2SO_4 and traces of Mg^{2+} (ca. 2000 ppm) and K^+ (ca. 100 – 200 ppm). The temperature profile and residence time in the kiln are controlled to obtain ZnS with an optimum particle size of ca. 300 nm.

The hot product from the kiln is quenched in water (e), passed via classifiers and hydroseparators (f) into thickeners (g), filtered on rotary filters (b_2), and washed until salt-free. The dried product is ground in high-intensity mills (g) and may undergo organic treatment (with a polyalcohol) depending on the application.

Figure 21 shows a scanning electron micrograph of lithopone. The ZnS and $BaSO_4$ particles can be distinguished by means of their size. The average particle diameter of $BaSO_4$ is 1 µm.

Figure 21. Scanning electron micrograph of lithopone. The larger particles are barium sulfate (mean size 1.0 µm) and the smaller particles are zinc sulfide (mean size 0.3 µm).

Sachtolith. Production is similar to that of lithopone. For process engineering reasons, a sodium sulfide solution is used as the sulfide component, and is formed according to Equation (4):

$$BaS + Na_2SO_4 \rightarrow Na_2S + BaSO_4 \quad (4)$$

The $BaSO_4$, which is produced as a byproduct, is filtered, washed, dried, and ground. It is a high-quality extender (Blanc fixe) used in the paint industry.

The Na_2S solution is mixed with a cobalt-treated zinc salt solution under precisely controlled conditions. The resulting zinc sulfide precipitate is calcined and processed to give the finished product.

Hydrothermal Process. Crystal growth of ZnS can be achieved by a hydrothermal process instead of by calcination. The raw lithopone is precipitated with a slight excess of sulfide at pH 8.5. The pH is then adjusted to 12 – 13 with sodium hydroxide solution, and 0.5 % sodium carbonate is added. The suspension is then autoclaved for ca. 15 – 20 min at 250 – 300 °C. In contrast to the wurtzite structure of the calcined product, the hydrothermal product has a sphalerite structure with a ca. 10 % greater scattering power. Although the product is of better quality, the hydrothermal process is less economic due to the high cost of the materials required for lining the autoclave (e.g., tantalum or a zirconium alloy).

Environmental Protection. During the reduction of barite and the calcination of Sachtolith and lithopone, sulfur dioxide is liberated. This is removed from the waste gas in a purification stage which is based on the reversible, temperature-dependent solubility of sulfur dioxide in polyglycol. The absorbed sulfur dioxide can be recovered as a liquid product or as a raw material for sulfuric acid. Any soluble barium in the residue from the dissolution of the fused BaS is removed by treatment with iron-containing waste hydrochloric acid. The gangue, in the form of a slime, is water-insoluble and can therefore be disposed of. The barium chloride solution is used as a raw material for the production of precipitated barium sulfate fillers.

2.2.3. *Commercial Products*

Commercial lithopone grades contain 30 % ZnS (red seal) and 60 % ZnS (silver seal). The ZnS content of Sachtolith is >97 %. Various chemical (e.g., polyalcohols, siloxanes, silanes) and mechanical treatments (e.g., jet milling) are used to obtain other products for special applications. The technical data for commercial red seal lithopone and Sachtolith are given in Table 20.

Table 20. Technical data for red seal lithopone and Sachtolith

Parameter	Standard	Sachtolith	Red seal lithopone
ZnS, wt %	DIN 55910	≥97	ca. 29
ZnO, wt %	DIN 55910	0.2	0.1
$BaSO_4$, wt %	DIN 55910	≤3	ca. 70
Brightness *		98	98 – 99
Lightening power	DIN 53192	400	120
Water-soluble salts, wt %	DIN 53197	< 0.2	< 0.2
Sieve residue **, wt %		0.02	< 0.1
Oil number	DIN 53192	12	8
pH	DIN 53200	6 – 8	7
Specific surface area, m^2/g		8	3

* $BaSO_4$ white standard=100.

** Test sieve 45 µm, DIN 4188, ISO DIS 3310/1.

2.2.4. *Uses*

Lithopone is mainly used in *coating materials* with relatively high pigment concentrations (Table 21). Examples are primers, plastic masses, putties and fillers, artists' colors, and emulsion paints. An important property of lithopone is its low binder requirement, giving paint products with good flow and application properties. It is suitable for almost all binder media, and has good wetting and dispersing properties. With optimum feed composition, good dispersion can be achieved simply by the action of a dissolver. It can be economically advantageous to use lithopone in combination with TiO_2 pigments; the good hiding power of the TiO_2 pigments is combined with the economic and technical advantages of lithopone. Due to the strong shift of the absorption band towards the blue, lithopone is especially useful as a white pigment for UV-cured paint systems. Zinc compounds have a fungicidal and algicidal action, and inclusion of lithopone or Sachtolith in paint formulations for exterior use therefore prevents attack by algae or fungi.

Table 21. Uses of Sachtolith and lithopone (as percentage of total consumption)

Use	Sachtolith	Lithopone	
		Western Europe	World
Paints	20	79	94
Plastics	64	17	2
Lubricants	6		
Others	10	4	4

The material advantages of lithopone are used in *plastics* (e.g., good lightfastness and clear bluish-white shade). The product also imparts very good extruding properties to the plastic resulting in high throughput rates and economic extruder operation. In fire-resistant systems, ca. 50 % of the flame retardant antimony trioxide can be replaced by nontoxic lithopone without any adverse effect.

Sachtolith is mainly used in plastics (Table 21). Functional properties such as lightening and hiding power are criteria for the use of Sachtolith. It has proved to be very useful for coloring many thermoplasts. During the dispersion process it does not cause abrasion of metallic production machinery or adversely effect the polymer, even at high operating temperatures or during multistage processing. Even ultrahigh molecular mass thermoplasts can be colored without problems. In glass-fiber-reinforced plastics, the soft texture of Sachtolith prevents mechanical fiber damage during extrusion. Sachtolith is also used as a dry lubricant during the fabrication of these materials.

The low abrasiveness of Sachtolith prolongs the operating life of stamping tools used in the manufacture of industrial rubber articles. The lightfastness and ageing resistance of many elastomers are improved by Sachtolith. It is also used as a dry lubricant for roller and plain bearings, and as a white pigment for greases and oils.

2.2.5. *Economic Aspects*

Total world production of lithopone in 1990 was 220×10^3 t. This was subdivided as follows (10^3 t):

Germany	30 (+7 Sachtolith)
Yugoslavia	5
Czechoslovakia	15
Soviet Union	50
People's Republic of China	120

Only estimated figures are available for the Soviet Union and the People's Republic of China.

A decrease in output is to be expected because replacement by TiO_2 is not yet at an end, especially in coating materials. In the long term, only the high-quality grades can maintain their place in the market, i.e., those in which technical properties are required in addition to light scattering.

2.2.6. *Toxicology*

The use of zinc sulfide and barium sulfate in contact with foods is permitted by the FDA (United States) and in most European countries. Some restrictions apply in France, Italy, the United Kingdom, and Czechoslovakia.

Soluble zinc is toxic in large amounts, but the human body requires small quantities (10 – 15 mg/d) for metabolism. Zinc sulfide is completely harmless in the human due to its low solubility. The acid concentration in the stomach and the rate of dissolution following ingestion are not sufficient to produce physiologically significant quantities of soluble zinc. LD_{50} values in the rat exceed 20 g/kg. No cases of poisoning or chronic damage to health have been observed in the manufacture of zinc sulfide pigments despite exposure to dust that occurs mainly during grinding and packing.

2.3. Zinc Oxide (Zinc White) [162-166]

2.3.1. *Introduction*

Zinc oxide [1314-13-2], ZnO, M_r 81.38, was formerly used only as a white pigment, and was named zinc white (C.I. Pigment White 4), Chinese white, or flowers of zinc. The term zinc white now denotes zinc oxide produced by the combustion of zinc metal according to the indirect or French process.

Historical Aspects. Zinc oxide has long been known as a byproduct of copper smelting. The Romans called it “cadmia” and used it as such in the production of brass. They also purified it for use in ointments by reduction followed by oxidation. In the Middle Ages, the alchemists thought that cadmia could be converted into gold.

In the mid-18th century, the German chemist CRAMER discovered that cadmia could be obtained by the combustion of metallic zinc. COURTOIS began to produce zinc white in 1781 in France, but it was not until 1840 that industrial production was started by LECLAIRE (indirect or French process). The use of this white pigment spread rapidly. Zinc oxide replaced white lead because it had the advantage of being nontoxic, of not darkening in the presence of sulfurous gases, and of having better hiding power.

Around 1850, S. WETHERILL of the New Jersey Zinc Company perfected a roasting furnace in which a grate was charged with coal and then covered with a mixture of zinc ore and coal. The zinc was reduced by the partial combustion of the coal and reoxidized at the furnace exit (direct or American process). These furnaces were subsequently improved but are now no longer used. During the second half of the nineteenth century, the use of ZnO in rubber was introduced to reduce the time needed for vulcanization. The discovery of the first organic accelerators for vulcanization in 1906 added to the importance of ZnO, which acts as an activator in these materials.

A third industrial production process exists but this wet process is less widely used.

2.3.2. *Properties*

Physical Properties. Zinc oxide is a fine white powder that turns yellow when heated above 300 °C. It absorbs UV light at wavelengths below 366 nm. Traces of monovalent or trivalent elements introduced into the crystal lattice impart semiconducting properties. The elementary particles of ZnO obtained by the thermal method may be granular or nodular (0.1 – 5 µm) or acicular (needle-shaped). Some physical properties are given below:

Density	5.65 – 5.68 g/cm^3
Refractive index	1.95 – 2.1
mp	1975 °C
Heat capacity	
25 °C	40.26 J mol^{-1} K^{-1}
100 °C	44.37 J mol^{-1} K^{-1}
1000 °C	54.95 J mol^{-1} K^{-1}
Thermal conductivity	25.2 W m^{-1} K^{-1}
Crystal structure	hexagonal, wurtzite
Mohs hardness	4 – 4.5

Chemical Properties. Zinc oxide is amphoteric; it reacts with organic and inorganic acids, and also dissolves in alkalis and ammonia solution to form zincates. It combines readily with acidic gases (e.g., CO_2, SO_2, and H_2S). It reacts at high temperatures with other oxides to form compounds such as zinc ferrites.

2.3.3. *Production*

About 1 – 2 % of zinc oxide is produced by the wet process, 10 – 20 % by the direct process, and the remainder by the indirect process.

Raw Materials. In the early days, the raw materials were mainly zinc ores or concentrates for the direct process, or metal from zinc producers for the indirect process. Nowadays, zinc oxide manufacturers mainly use residues and secondary zinc. This fact, combined with the demand for chemical purity imposed by the users, means that processes have had to be modified and a number of purification techniques are used.

Direct or American Process. The direct process is noted for its simplicity, low cost, and excellent thermal efficiency. It consists of an initial high-temperature reduction (1000 – 1200 °C) of a zinc-containing material (as oxide), the reducing agent being coal. Reduction takes place according to Boudouard's equations:

$$ZnO + C \rightleftharpoons Zn + CO$$

$$ZnO + CO \rightleftharpoons Zn + CO_2$$

$$C + O_2 \rightleftharpoons CO_2$$

$$CO_2 + C \rightleftharpoons 2CO$$

The zinc vapor and the CO gas are then oxidized to zinc oxide and carbon dioxide above the reaction bed or at the furnace exit. Various zinc-containing materials are used, e.g., zinc concentrates, metallization residues, byproduct zinc hydroxide, and above all zinc dross from casting furnaces or galvanizing. The dross must first be treated to remove chloride and lead by heating at ca. 1000 °C in rotary kilns.

Only rotary kilns are now used for the direct process; the use of static furnaces has been discontinued. The zinc content of raw materials is between 60 and 75 %. There are two types of rotary kiln:

1. One type is a long (ca. 30 m), fairly narrow (2.5 m diameter) kiln, heated by gas or oil. The raw material (a mixture of zinc-containing material and coal) is charged continuously either countercurrent or cocurrent to the combustion gases. The residues, which still contain some zinc and unburned coal, leave the furnace continuously at the end opposite to the feed end. The excess coal is sieved out and recycled. The combustion gases, containing zinc vapor, ZnO, and CO, pass into a chamber where oxidation is completed and large particles of impurities settle out. The gases are then cooled in a heat exchanger or by dilution with air. The zinc oxide is collected in bag filters.

2. The second type of rotary kiln is shorter (5 m) and has a larger diameter (ca. 3 m). Charging is continuous, but the dezincified residues are removed batchwise.

In both cases, operating conditions are controlled to obtain a high yield and to give the required particle shape and size. Provided no contamination is introduced, chemical purity is determined solely by the composition of the raw materials used.

Indirect or French Process. The zinc is boiled, and the resulting vapor is oxidized by combustion in air under defined conditions. The crystallographic and physical properties of the ZnO can be controlled by adjustment of the combustion conditions (e.g., flame turbulence and air excess). The chemical composition of the ZnO is solely a function of the composition of the zinc vapor.

Many types of furnace are available to produce vapor of the required purity from various raw materials and obtain a high yield of zinc. Pure zinc (super high grade, SHG; high grade, HG) or, to an increasing extent, metal residues (e.g., scrap zinc, die casting dross, or galvanizer's dross) are used as raw materials. Various liquid- or vapor-phase separation techniques are used for separating Cd, Pb, Fe, and Al from zinc metal before it is oxidized.

1. *Muffle Furnaces or Retorts of Graphite or Silicon Carbide.* The metal is fed into the furnace either batchwise as a solid or continuously as a liquid. The heat of vaporization is supplied by heating the outside of the retort with a burner. The nonvolatile residues (iron and lead in the case of dross from smelting) accumulate in the retort and must be removed at intervals. This is facilitated by tipping the retorts.
2. *Fractional Distillation.* The vapor, containing Cd, Pb, Fe, Al, and Cu, can be purified by fractional distillation in columns (New Jersey Zinc Co.) with silicon carbide plates. Oxidation takes place at the exit of the column.
3. *Furnaces with Two Separate Chambers.* The metallic raw material, which can be in large pieces, is fed into the first chamber where it melts. This is connected to the second, electrically heated chamber where distillation takes place in the absence of air. The first version of this type of furnace was constructed by LUNDEVALL [167]. The nonmetallic residues are removed at the surface of the melting chamber. Impurities, such as Fe, Al, and some of the Pb, accumulate in the distillation chamber and are periodically removed in the liquid state. The last traces of lead are then removed by fractional distillation.
4. *Smelting Process in a Rotary Kiln.* Indirect zinc oxide is also made by smelting in a rotary kiln, starting from the same raw materials. Melting, distillation, and part of the oxidation all take place in the same zone, allowing utilization of a large part of the heat of combustion of the zinc. By controlling the temperature and partial pressures of carbon dioxide and oxygen, the impurity content (Pb) can be limited and the shape and size of the ZnO particles can be adjusted, though to a lesser extent than in the other processes.

Wet Process. Zinc oxide is also produced industrially from purified solutions of zinc sulfate or chloride by precipitating the basic carbonate, which is then washed, filtered, and finally calcined. This method produces a grade of zinc oxide with a high specific surface area.

Products of this type are also obtained from waste hydroxides which are purified by a chemical route and then calcined.

Aftertreatment. Thermal treatment at temperatures up to 1000 °C improves the pigment properties of the ZnO and is mainly applied to oxide produced by the direct method. Controlled atmospheric calcination also improves the photoconducting properties of the high-purity oxide used in photocopying.

The ZnO surface is made more organophilic by coating it with oil and propionic acid. The ZnO is often deaerated and sometimes pelletized or granulated to improve handling properties.

2.3.4. *Quality Specifications*

Many standard specifications have been laid down for the more important uses of ZnO (rubber, paints, and the pharmaceutical industry). For standards, see Table 1 ("Zinc oxide pigments; Methods of analysis" and "Specification"). Various methods of classification are used, often based on the production process and the chemical composition. The most well-known are pharmacopeias, RAL 844 C3 (Reichs-Ausschuß für Lieferbedingungen), ASTM D79, BS 254, DAB 8, T 31 006 NF (French standard), and ISO R 275. Table 22 shows the classification of commercially available zinc oxide grades.

Table 22. Classification of commercially available grades of zinc oxide

Parameter	A	B	C	D
	Indirect process	Indirect process	Direct process	Wet process
ZnO (min.), wt %	99.5	99	98.5	93
Pb (max.), wt %	0.004	0.25	0.25	0.001
Cd (max.), wt %	0.001	0.05	0.03	0.001
Cu (max.), wt %	0.0005	0.003	0.005	0.001
Mn (max.), wt %	0.0005	0.001	0.005	0.001
Water-soluble salts (max.), wt %	0.02	0.1	0.65	1
Loss on ignition (max.), wt %	0.3	0.3	0.3	4
Acidity, g H_2SO_4/100 g	0.01	0.1	0.3	0.2
Specific surface area, m^2/g	3 – 8	3 – 10	1 – 5	25 (min.)

Classification based on color codes is common in Europe, but is of limited value. Manufacturers have their own standards. In general, the terms silver seal and white seal indicate category A, and red seal category B.

2.3.5. *Uses*

Zinc oxide has many uses. By far the most important is in the *rubber industry*. Almost half the world's ZnO is used as an activator for vulcanization accelerators in natural and synthetic rubber. The reactivity of the ZnO is a function of its specific surface area, but is also influenced by the presence of impurities such as lead and sulfates. The ZnO also ensures good durability of the vulcanized rubber, and increases its thermal conductivity. The ZnO content is usually 2 – 5 %.

In *paints and coatings*, zinc oxide is no longer the principal white pigment, although its superb white color is used by artists (⟶ Artists' Colors – Colored Inorganic Pigments). It is used as an additive in exterior paints for wood preservation. It is also utilized in antifouling and anticorrosion paints [168]. It improves film formation, durability, and resistance to mildew (having a synergistic effect with other fungicides) because it reacts with acidic products of oxidation and can absorb UV radiation.

The *pharmaceutical and cosmetic industries* use ZnO in powders and ointments because of its bactericidal properties. It is also used to form dental cements by its reaction with eugenol (⟶ Dental Materials).

In the field of *glass, ceramics, and enamels*, ZnO is used for its ability to reduce thermal expansion, to lower the melting point, and to increase chemical resistance. It can also be used to modify gloss or to improve opacity.

Zinc oxide is used as a *raw material* for many products: stearates, phosphates, chromates, bromates, organic dithiophosphates, and ferrites (ZnO, MnO, Fe_2O_3). It is used as a source of zinc in animal feeds and in electrogalvanization (⟶ Electrochemical and Chemical Deposition – Zinc Deposits). It is also used for desulfurizing gases.

Zinc oxide is used as a *catalyst* in organic syntheses (e.g., of methanol), often in conjunction with other oxides. It is present in some adhesive compositions.

The highest purity material is calcined with additives such as Bi_2O_3 and used in the manufacture of varistors (⟶ Ceramics, Electronic) [169]. The photoconducting properties of ZnO are used in photoreproduction processes. Doping with alumina causes a reduction in electrical resistance; hence, it can be used in the coatings on the master papers for offset reproduction [170].

2.3.6. *Economic Aspects*

The consumption of zinc oxide in Western Europe in 1990 was estimated to be 160 000 t. Annual world consumption is in the region of 500 000 t, representing ca. 10 % of the total world zinc production. The rubber industry consumes ca. 45 % of the total and the remainder is divided among a large number of industries.

2.3.7. *Toxicology and Occupational Health*

Unlike other heavy metals, zinc is not considered to be toxic or dangerous. It is an essential element for humans, animals, and plants. The human body contains ca. 2 g, and it is recommended that 10 – 20 mg should be ingested per day [171]. The oral LD_{50} value for rats is 630 mg/kg. The permitted concentration of the dust in air at the

workplace is 5 mg/m^3 (MAK), 10 mg/m^3 (TLV-TWA). Values for zinc oxide fumes are 5 mg/m^3(TLV-TWA) and 10 mg/m^3 (TLV-STEL).

If large quantities of ZnO are accidentally ingested or inhaled, fever, nausea, and irritation of the respiratory tract ensue after several hours. These symptoms rapidly disappear without long-term consequences.

[Top of Page]

3. Colored Pigments

Gunter Buxbaum, Helmut Printzen, Manfred Mansmann, Dieter Räde, Gerhard Trenczek, Volker Wilhelm, Stefanie Schwarz, Henning Wienand, Jörg Adel, Gerhard Adrian, Karl Brandt, William B. Cork, Heinrich Winkeler, Wielfried Mayer, Klaus Schneider

Colored pigments differ from black and white pigments in that their absorption and scattering coefficients are wavelength dependent with widely varying absolute values. The dependence of these coefficients on wavelength, particle size, particle shape, and their distributions determine the color, tinting strength, and hiding power of the pigments (see Section Fundamental Aspects).

3.1. Oxides and Hydroxides

In many inorganic pigments, lanthanides and transition elements are responsible for color. Metal oxides and oxide hydroxides are, however, also important as colored pigments because of their optical properties, low price, and ready availability. Colored pigments based on oxides and oxide hydroxides are either composed of a single component or mixed phases. In the latter, color is obtained by incorporation of appropriate cations.

3.1.1. *Iron Oxide Pigments*

The continually increasing importance of iron oxide pigments is based on their nontoxicity; chemical stability; wide variety of colors ranging from yellow, orange, red, brown, to black; and low price. Natural and synthetic iron oxide pigments consist of well-defined compounds with known crystal structures [172]:

1. α-FeOOH, goethite [1310-14-1], diaspore structure, color changes with increasing particle size from green-yellow to brown-yellow
2. ϒ-FeOOH, lepidocrocite [12022-37-6], boehmite structure, color changes with increasing particle size from yellow to orange
3. α-Fe_2O_3, hematite [1317-60-8], corundum structure, color changes with increasing particle size from light red to dark violet
4. ϒ-Fe_2O_3, maghemite [12134-66-6], spinel super structure, ferrimagnetic, color: brown
5. Fe_3O_4, magnetite [1309-38-2], spinel structure, ferrimagnetic, color: black

Mixed metal oxide pigments containing iron oxide are also used (see Section Mixed Metal Oxide Pigments). Magnetic iron oxide pigments are discussed in Sections Iron Oxide Pigments and Cobalt-Containing Iron Oxide Pigments. Transparent iron oxide pigments are described in Section Transparent Iron Oxides. Methods of analysis and specifications of iron oxide pigments are listed in the standards given in Table 1.

3.1.1.1. *Natural Iron Oxide Pigments*

Naturally occurring iron oxides and iron oxide hydroxides were used as pigments in prehistoric times (Altamira cave paintings) [173]. They were also used as coloring materials by the Egyptians, Greeks, and ancient Romans.

Hematite (α-Fe_2O_3) has attained economic importance as a red pigment, goethite (α-FeOOH) as yellow, and the umbers and siennas as brown pigments. Deposits with high iron oxide contents are exploited preferentially. Naturally occurring magnetite (Fe_3O_4) has poor tinting strength as a black pigment, and has found little application in the pigment industry.

Hematite is found in large quantities in the vicinity of Malaga in Spain (Spanish red) and near the Persian Gulf (Persian red). The Spanish reds have a brown undertone. Their water-soluble salt content is very low and their Fe_2O_3 content often exceeds 90 %. The Persian reds have a pure hue, but their water-soluble salt content is disadvantageous for some applications. Other natural hematite deposits are of only local importance. A special variety occurs in the form of platelets and is extracted in large quantities in Kärnten (Austria). This micaceous iron oxide, is mainly used in corrosion protection coatings.

Goethite is the colored component of yellow ocher; a weathering product mainly of siderite, sulfidic ores, and feldspar. It occurs in workable amounts mainly in the Republic of South Africa and France. The Fe_2O_3 content gives an indication of the iron oxide hydroxide content of the ocher, and is ca. 20 % in the French deposits and ca. 55 % in the South African.

Umbers are mainly found in Cyprus. In addition to Fe_2O_3 (45 – 70 %), they contain considerable amounts of manganese dioxide (5 – 20 %). In the raw state, they are deep brown to greenish brown and when calcined are dark brown with a red undertone (burnt umbers).

Siennas, mainly found in Tuscany, have an average Fe_2O_3 content of ca. 50 %, and contain < 1 % manganese dioxide. They are yellow-brown in the natural state and red-brown when calcined [174].

The processing of natural iron oxide pigments depends on their composition. They are either washed, slurried, dried, ground, or dried immediately and then ground in ball mills, or more often in disintegrators or impact mills (see ⟶ Size Reduction – Grinding Media Mills, ⟶ Size Reduction) [175].

Siennas and umbers are calcined in a directly fired furnace, and water is driven off. The hue of the products is determined by the calcination period, temperature, and raw material composition [176].

Natural iron oxide pigments are mostly used as inexpensive marine coatings or in coatings with a glue, oil, or lime base. They are also employed to color cement, artificial stone, and wallpaper. Ocher and sienna pigments are used in the production of crayons, drawing pastels, and chalks [177].

For standards, see Table 1 (Iron, manganese oxide pigments: “Methods of analysis”; “Natural, specification”; “Sienna, specification”; and “Umber, specification”).

The economic importance of the natural iron oxide pigments has decreased in recent years in comparison with the synthetic materials.

3.1.1.2. *Synthetic Iron Oxide Pigments*

Synthetic iron oxide pigments have become increasingly important due to their pure hue, consistent properties, and tinting strength. Single- component forms are mainly produced with red, yellow, orange, and black colors. Their composition corresponds to that of the minerals hematite, geothite, lepidocrocite, and magnetite. Brown pigments usually consist of mixtures of red and/or yellow and/or black; homogeneous brown phases are also produced, e.g., $(Fe, Mn)_2O_3$ and ϒ-Fe_2O_3, but quantities are small in comparison to the mixed materials. Ferrimagnetic ϒ-Fe_2O_3 is of great importance for magnetic recording materials (see Sections Iron Oxide Pigments and Cobalt-Containing Iron Oxide Pigments).

Several processes are available for producing high-quality iron oxide pigments with controlled mean particle size, particle size distribution, particle shape, etc. (Table 23):

1. Solid-state reactions (red, black, brown)
2. Precipitation and hydrolysis of solutions of iron salts (yellow, red, orange, black)
3. Laux process involving reduction of nitrobenzene (black, yellow, red)

Table 23. Reaction equations for the production of iron oxide pigments

Color	Reaction		Process
Red	$6\ FeSO_4 \cdot x\ H_2O + 1½\ O_2$	⟶ $Fe_2O_3 + 2\ Fe_2(SO_4)_3 + 6\ H_2O$	copperas process
	$2\ Fe_2(SO_4)_3$	⟶ $2\ Fe_2O_3 + 6\ SO_3$	
	$2\ Fe_3O_4 + ½\ O_2$	⟶ $3\ Fe_2O_3$	calcination
	2 FeOOH	⟶ $Fe_2O_3 + H_2O$	calcination
		⟶	Ruthner process

	$2\ FeCl_2+2\ H_2O+½\ O_2$	$Fe_2O_3+4\ HCl$	
	$2\ FeSO_4+½\ O_2+4\ NaOH$	$\longrightarrow Fe_2O_3+2\ Na_2SO_4+2\ H_2O$	precipitation
Yellow	$2\ FeSO_4+4\ NaOH+½\ O_2$	$\longrightarrow 2\ \alpha\text{-FeOOH}+2\ Na_2SO_4+H_2O$	precipitation
	$2\ Fe+2\ H_2SO_4$	$\longrightarrow 2\ FeSO_4+2\ H_2$	Penniman process
	$2\ FeSO_4+½\ O_2+3\ H_2O$	$\longrightarrow 2\ \alpha\text{-FeOOH}+2\ H_2SO_4$	
	$2\ Fe+½\ O_2+3\ H_2O$	$\longrightarrow 2\ \alpha\text{-FeOOH}+2\ H_2$	
	$2\ Fe+C_6H_5NO_2+2\ H_2O$	$\longrightarrow 2\ \alpha\text{-FeOOH}+C_6H_5NH_2$	Laux process
Orange	$2\ FeSO_4+4\ NaOH+½\ O_2$	$\longrightarrow 2\ \gamma\text{-FeOOH}+2\ Na_2SO_4+H_2O$	precipitation
Black	$3\ FeSO_4+6\ NaOH+½\ O_2$	$\longrightarrow Fe_3O_4+3\ Na_2SO_4+3\ H_2O$	1-step precipitation
	$2\ FeOOH+FeSO_4+2\ NaOH$	$\longrightarrow Fe_3O_4+Na_2SO_4+2\ H_2O$	2-step precipitation
	$9\ Fe+4\ C_6H_5NO_2+4\ H_2O$	$\longrightarrow 3\ Fe_3O_4+4\ C_6H_5NH_2$	Laux process
	$3\ Fe_2O_3+H_2$	$\longrightarrow 2\ Fe_3O_4+H_2O$	reduction
Brown	$2\ Fe_3O_4+½\ O_2$	$\longrightarrow 3\ \gamma\text{-}Fe_2O_3$	calcination
	$3\ Fe_3O_4+Fe_2O_3+MnO_2+½\ O_2$	$\longrightarrow (Fe_{11},Mn)O_{18}$	calcination

The raw materials are mainly byproducts from other industries: steel scrap obtained from deep drawing, grindings from cast iron, $FeSO_4 \cdot 7\ H_2O$ from TiO_2 production or from steel pickling, and $FeCl_2$ also from steel pickling.

Iron oxides obtained after flame spraying of spent hydrochloric acid pickle liquor, red mud from bauxite processing, and the product of pyrites combustion are no longer of importance. They yield pigments with inferior color properties that contain considerable amounts of water-soluble salts. They can therefore only be used in low-grade applications.

Solid-State Reactions of Iron Compounds. Black iron oxides obtained from the Laux process (see below) or other processes may be calcined in rotary kilns with an oxidizing atmosphere under countercurrent flow to produce a wide range of different red colors, depending on the starting material. The pigments are ground to the desired particle size in pendular mills, pin mills, or jet mills, depending on their hardness and intended use.

The calcination of yellow iron oxide produces pure red iron oxide pigments with a high tinting strength. Further processing is similar to that of calcined black pigments.

High-quality pigments called copperas reds are obtained by the thermal decomposition of $FeSO_4 \cdot 7\ H_2O$ in a multistage process (Fig. 22). If an alkaline-earth oxide or carbonate is included during calcination, the sulfate can be reduced with coal or carbon- containing compounds to produce sulfur dioxide, which is oxidized with air to give sulfuric acid [178-181]. The waste gases and the dissolved impurities that are leached out in the final stage present ecological problems, however.

Figure 22. Production of copperas red

a) Dryer; b) Rotary kiln (dewatering); c) Rotary kiln; d) Tank; e) Thickener; f) Filter

Lower quality products can be obtained by single-stage calcination of iron(II) sulfate heptahydrate in an oxidizing atmosphere. The pigments have a relatively poor tinting strength and a blue tinge. Decomposition of iron(II) chloride monohydrate in air at high temperatures also yields a low-quality red iron oxide pigment [182].

In a new process, micaceous iron oxide is obtained in high yield by reacting iron(III) chloride and iron at 500 – 1000 °C in an oxidizing atmosphere in a tubular reactor [183].

Black Fe_3O_4 pigments with a high tinting strength can be prepared by calcining iron salts under reducing conditions [184]. This process is not used industrially because of the furnace gases produced.

Controlled oxidation of Fe_3O_4 at ca. 500 °C produces a single-phase brown $\gamma\text{-}Fe_2O_3$ with a neutral hue [185].

Calcination of α-FeOOH with small quantities of manganese compounds gives homogeneous brown pigments with the composition $(Fe, Mn)_2O_3$ [186]. Calcination of iron and chromium compounds that decompose at elevated temperatures yields corresponding pigments with the composition $(Fe, Cr)_2O_3$ [187].

Precipitation Processes. In principle, all iron oxide hydroxide phases can be prepared from aqueous solutions of iron salts (see Table 23). However, precipitation with alkali produces neutral salts (e.g., Na_2SO_4, NaCl) as byproducts which enter the wastewater.

Precipitation is especially suitable for producing soft pigments with a pure, bright hue. The manufacture of α-FeOOH yellow is described as an example. The raw materials are iron(II) sulfate ($FeSO_4 \cdot 7\ H_2O$) or liquors from the pickling of iron and steel (⟶ Iron Compounds), and alkali [NaOH, $Ca(OH)_2$, ammonia, or magnesite]. The pickle liquors usually contain appreciable quantities of free acid, and are therefore first optionally neutralized by reaction with scrap iron. Other metallic ions should not be present in large amounts, because they have an adverse effect on the hue of the iron oxide pigments.

The solutions of the iron salts are first mixed with alkali in open reaction vessels (Fig. 23 Route A) and oxidized, usually with air. The quantity of alkali used is such that the pH remains acidic. The reaction time (ca. 10 – 100 h) depends on the temperature (10 – 90 °C) and on the desired particle size of the pigment. This method yields yellow pigments (α-FeOOH) [188], [189]. If yellow nuclei are produced in a separate reaction (Route A in Fig. 23, tank c), highly consistent yellow iron oxide pigments with a pure color can be obtained [190].

Figure 23. Production of yellow iron oxide by the precipitation (A) and Penniman (B) processes

a) Tank; b) Pigment reactor; c) Seed reactor; d) Pigment reactor with scrap basket; e) Filter; f) Dryer; g) Mill

If precipitation is carried out at ca. 90 °C while air is passed into the mixture at ca. pH≥7, black iron oxide pigments with a magnetite structure and a good tinting strength are obtained when the reaction is stopped at a FeO : Fe_2O_3 ratio of ca. 1:1. The process can be accelerated by operating at 150 °C under pressure; this technique also improves pigment quality [191]. Rapid heating of a suspension of iron oxide hydroxide with the necessary quantity of $Fe(OH)_2$ to ca. 90 °C also produces black iron oxide of

pigment quality [192], [193].

Orange iron oxide with the lepidocrocite structure (γ-FeOOH) is obtained if dilute solutions of the iron(II) salt are precipitated with sodium hydroxide solution or other alkalis until almost neutral. The suspension is then heated for a short period, rapidly cooled, and oxidized [194], [195].

Very soft iron oxide pigments with a pure red color may be obtained by first preparing α-Fe_2O_3 nuclei, and then continuously adding solutions of iron(II) salt with atmospheric oxidation at 80 °C. The hydrogen ions liberated by oxidation and hydrolysis are neutralized by adding alkali and keeping the pH constant [196]. Pigment-quality α-Fe_2O_3 is also obtained when solutions of an iron(II) salt, preferably in the presence of small amounts of other cations, are reacted at 60 – 95 °C with excess sodium hydroxide and oxidized with air [197].

Penniman process. The *Penniman process* is probably the most widely used production method for yellow iron oxide pigments [198], [199]. This method considerably reduces the quantity of neutral salts formed as byproducts. The raw materials are iron(II) sulfate, sodium hydroxide solution, and scrap iron. If the sulfate contains appreciable quantities of salt impurities, these must be removed by partial precipitation. The iron must be free of alloying components. The process usually consists of two stages (Route B in Fig. 23).

In the first stage, nuclei are prepared by precipitating iron(II) sulfate with alkali (e.g., sodium hydroxide solution) at 20 – 50 °C with aeration (c). Depending on the conditions, yellow, orange, or red nuclei may be obtained. The suspension of nuclei is pumped into vessels charged with scrap iron (d) and diluted with water. Here, the process is completed by growing the iron oxide hydroxide or oxide onto the nuclei. The residual iron(II) sulfate in the nuclei suspension is oxidized to iron(III) sulfate by blasting with air at 75 – 90 °C. The iron(III) sulfate is then hydrolyzed to form FeOOH or α-Fe_2O_3. The liberated sulfuric acid reacts with the scrap iron to form iron(II) sulfate, which is also oxidized with air. The reaction time can vary from ca. two days to several weeks, depending on the conditions chosen and the desired pigment. At the end of the reaction, metallic impurities and coarse particles are removed from the solid with sieves or hydrocyclones; water-soluble salts are removed by washing. Drying is carried out with band or spray dryers (f) and disintegrators or jet mills are used for grinding (g). The main advantage of this process over the precipitation process lies in the small quantity of alkali and iron(II) sulfate required. The bases are only used to form the nuclei and the relatively small amount of iron(II) sulfate required initially is continually renewed by dissolving the iron by reaction with the sulfuric acid liberated by hydrolysis. The process is thus considered environmentally friendly. The iron oxide pigments produced by the Penniman process are soft, have good wetting properties, and a very low flocculation tendency [198-206].

Under suitable conditions the Penniman process can also be used to produce reds directly. The residual scrap iron and coarse particles are removed from the pigment, which is then dried [207] and ground using disintegrators or jet mills. These pigments have unsurpassed softness. They usually have purer color than the harder red pigments produced by calcination.

The Laux Process. The Béchamp reaction (i.e., the reduction of aromatic nitro compounds with antimony or iron) which has been known since 1854, normally yields a black-gray iron oxide that is unsuitable as an inorganic pigment. By adding iron(II) chloride or aluminum chloride solutions, sulfuric acid, and phosphoric acid, LAUX modified the process to yield high-quality iron oxide pigments [208]. Many types of pigments can be obtained by varying the reaction conditions. The range extends from yellow to brown (mixtures of α-FeOOH and/or α-Fe_2O_3 and/or Fe_3O_4) and from red to black. If, for example, iron(II) chloride is added, a black pigment with very high tinting strength is produced [208]. However, if the nitro compounds are reduced in the presence of aluminum chloride, high-quality yellow pigments are obtained [209]. Addition of phosphoric acid leads to the formation of light to dark brown pigments with good tinting strength [210]. Calcination of these products (e.g., in rotary kilns) gives light red to dark violet pigments. The processes are illustrated in Figure 24.

Figure 24. Production of iron oxide pigment by the Laux process

a) Reactor; b) Condenser; c) Classifier; d) Thickener; e) Filter; f) Dryer; g) Mill; h) Rotary kiln

The type and quality of the pigment are determined not only by the nature and concentration of the additives, but also by the reaction rate. The rate depends on the grades of iron used, their particle size, the rates of addition of the iron and nitrobenzene (or another nitro compound), and the pH value. No bases are required to precipitate the iron compounds. Only ca. 3 % of the theoretical amount of acid is required to dissolve all of the iron. The aromatic nitro compound oxidizes the Fe^{2+} to Fe^{3+} ions, acid is liberated during hydrolysis and pigment formation, and more metallic iron is dissolved by the liberated acid to form iron(II) salts; consequently, no additional acid is necessary.

The iron raw materials used are grindings from iron casting or forging that must be virtually free of oil and grease. The required fineness is obtained by size reduction in edge runner mills and classification with vibratory sieves. The iron and the nitro compound are added gradually via a metering device to a stirred tank (a) containing the other reactants (e.g., iron(II) chloride, aluminum chloride, sulfuric acid, and phosphoric acid). The system rapidly heats up to ca. 100 °C and remains at this temperature for the reaction period. The nitro compound is reduced to form an amine (e.g., aniline from nitrobenzene) which is removed by steam distillation. Unreacted iron is also removed (e.g., in shaking tables, c). The pigment slurry is diluted with water in settling tanks (d) and the pigment is washed to remove salts, and filtered on rotary filters (e). It may then be dried on band, pneumatic conveyor, or spray dryers to form yellow or black pigments, or calcined in rotary kilns (h) in an oxidizing atmosphere to give red or brown pigments. Calcination in a nonoxidizing atmosphere at 500 – 700 °C improves the tinting strength [211]. The pigments are then ground to the desired fineness in pendular mills, pin mills, or jet mills, depending on their hardness and application.

The Laux process is a very important method for producing iron oxide because of the coproduction of aniline; it does not generate byproducts that harm the environment.

Other Production Processes. The three processes already described are the only ones that are used on a large scale. The following processes are used on a small scale for special applications:

1. Thermal decomposition of $Fe(CO)_5$ to form transparent iron oxides (see Section Transparent Pigments) [212]
2. Hydrothermal crystallization for the production of α-Fe_2O_3 in platelet form [213]

3.1.1.3. *Toxicology and Environmental Aspects*

The Berufsgenossenschaft der Chemischen Industrie (Germany) has recommended that all iron oxide pigments should be classified as inert fine dusts with an MAK value of 6 mg/m^3. A substantial decrease is under consideration.

Iron oxide pigments produced from pure starting materials may be used as colorants for food and pharmaceutical products [214]. Synthetic iron oxides do not contain crystalline silica and therefore are not considered to be toxic, even under strict Californian regulations.

3.1.1.4. *Quality*

The red and black iron oxide pigments produced by the methods described have an Fe_2O_3 content of 92 – 96 wt %. For special applications (e.g., ferrites) analytically pure pigments with Fe_2O_3 contents of 99.5 – 99.8 wt % are produced. The Fe_2O_3 content of yellow and orange pigments lies between 85 and 87 wt % corresponding to FeOOH contents of 96 – 97 wt %. For standards, see Table 1 (Iron oxide pigments: “Black, specification”; “Red, specification”; “Yellow, specification”; and “FeO content”). Variations of 1 – 2 % are of no importance with respect to the quality of the pigments. Pigment quality is mainly determined by the quantity and nature of the water-soluble salts, the particle size distribution (hue and tinting strength are effected) and the average particle size of the ground product. The hue of red iron oxide is determined by the particle diameter, which is ca. 0.1 µm for red oxides with a yellow tinge and ca. 1.0 µm for violet hues.

The optical properties of the yellow, usually needle-shaped, iron oxide pigments depend not only on the particle size, but also on the length to width ratio (e.g., length = 0.3 – 0.8 µm, diameter = 0.05 – 0.2 µm, length: diameter ratio = ca. 1.5 – 8). In applications for which needle-shaped particles are unsuitable, spheroidal pigments are available [215]. Black iron oxide pigments (Fe_3O_4) have a particle diameter of ca. 0.1 – 0.6 µm.

Some iron oxide pigments have a limited stability on heating. Red iron oxide is stable up to 1200 °C in air. In the presence of oxygen, black iron oxide changes into brown γ-Fe_2O_3 at ca. 180 °C and then into red α-Fe_2O_3 above 350 °C. Yellow iron oxide decomposes above ca. 180 °C to form red α-Fe_2O_3 with liberation of water. This temperature limit can be increased to ca. 260 °C by stabilization with basic aluminum compounds. The thermal behavior of brown iron oxides produced by mixing depends on their composition.

3.1.1.5. *Uses*

All synthetic iron oxides possess good tinting strength and excellent hiding power. They are also lightfast and resistant to alkalis. These properties are responsible for their versatility. The principle areas of use are shown in Table 24.

Table 24. Main areas of use for natural and synthetic iron oxide pigments

Use	Amount, %		
	Europe	United States	World
Coloring construction materials	64	37	60
Paints and coatings	30	48	29
Plastics and rubber	4	14	6
Miscellaneous	2	1	5

Iron oxide pigments have long been used for coloring construction materials. Concrete roof tiles, paving bricks, fibrous cement, bitumen, mortar, rendering, etc. can be colored with small amounts of pigment that do not affect the setting time, compression strength, or tensile strength of the construction materials. Synthetic pigments are superior to the natural pigments due to their better tinting power and purer hue.

Natural rubber can only be colored with iron oxides that contain very low levels of copper and manganese (Cu < 0.005 %, Mn < 0.02 %). Synthetic rubber is less sensitive.

In the paint and coating industries, iron oxide pigments can be incorporated in many types of binders. Some reasons for their wide applicability in this sector are pure hue, good hiding power, good abrasion resistance, and low settling tendency. Their high temperature resistance allows them to be used in enamels.

The use of iron oxide as a polishing medium for plate glass manufacture has decreased now that other methods of glass production are available.

3.1.1.6. *Economic Aspects*

Accurate production figures for natural and synthetic iron oxide pigments are difficult to obtain, because statistics also include nonpigmentary oxides (e.g., red mud from bauxite treatment, intermediate products used in ferrite production). World production of synthetic iron oxides in 1995 was estimated to be 600 000 t; production of natural oxides was ca. 100 000 t. The most important producing countries for synthetic pigments are Germany, the United States, Italy, Brazil, China, and Japan. The natural oxides are mainly produced in France, Spain, Cyprus, India, Iran, Italy, and Austria.

The most important *manufacturers* are Bayer, Elementis, Laporte, and Toda.

3.1.2. *Chromium Oxide Pigments*

See also ⟶ Chromium Compounds – Chromium(III) Oxide and Chromium Hydroxide.

Chromium oxide pigments, also called chromium oxide green pigments, consist of chromium(III) oxide [1308-38-9], Cr_2O_3, M_r 151.99. Chromium oxide green is one of the few single- component pigments with green coloration. Chrome green is a blend of chrome yellow and iron blue pigments; phthalochrome green is a blend of chrome yellow and blue phthalocyanine pigments.

Natural, minable deposits of chromium oxide are not known. In addition to pigment grade, chromium oxide producers usually also offer a technical grade for applications based on properties other than coloration. These include:

1. Metallurgy: aluminothermic production of chromium metal (⟶ Chromium and Chromium Alloys)
2. Refractory industry: production of thermally and chemically resistant bricks and lining materials
3. Ceramic industry: coloring of porcelain enamels, ceramic frits, and glazes
4. Pigment industry: raw material for the production of chromium- containing stains and pigments based on mixed metal oxide phases (⟶ Ceramic Colorants, see also Section Mixed Metal Oxide Pigments)
5. Grinding and polishing agent: chromium (III) oxide is used in brake linings and polishing agents due to its high hardness

Chromium oxide hydroxide and hydrated chromium oxide pigments (Grignets Green) have a very attractive blue-green color. They are of low opacity, but provide excellent lightfastness and good chemical resistance. Loss of water on heating limits the application temperature. These pigments are no longer of industrial importance [216].

3.1.2.1. *Properties*

Chromium(III) oxide crystallizes in the rhombohedral structure of the corundum type; space group D^6_{3d}-$R\bar{3}$ c, ϱ 5.2 g/cm^3. Because of its high hardness (ca. 9 on the Mohs scale) the abrasive properties of the pigment must be taken into account in certain applications [217]. It melts at 2435 °C but starts to evaporate at 2000 °C. Depending on the manufacturing conditions, the particle sizes of chromium oxide pigments are in the range 0.1 – 3 µm with mean values of 0.3 – 0.6 µm. Most of the particles are isometric. Coarser chromium oxides are produced for special applications, e.g., for applications in the refractory area.

Chromium oxide has a refractive index of ca. 2.5. Chromium oxide green pigments have an olive green tint. Lighter greens with yellowish hues are obtained with finely divided pigments, and darker, bluish tints with larger particle diameters; the darker pigments are weaker colorants. The maximum of the reflectance curve lies in the green region of the spectrum at ca. 535 nm (Fig. 25, curve a). A weaker maximum in the violet region (ca. 410 nm) is caused by Cr – Cr interactions in the crystal lattice. Chromium oxide green pigments are used in IR-reflecting camouflage coatings because of their relatively high reflectance in the near infrared (Fig. 25, curve b).

Figure 25. Dependence of the reflectance of chromium oxide on the wavelength

a) Regular pigment; b) Special product with larger particle size and high IR reflectance

Since chromium(III) oxide is virtually inert, chromium oxide green pigments are remarkably stable. They are insoluble in water, acid, and alkali and are thus extremely stable to sulfur dioxide and in concrete. They are light-, weather-, and temperature-resistant. A change of the tint only occurs above 1000 °C due to particle growth.

3.1.2.2. *Production*

Alkali dichromates are used as starting materials for the production of chromium(III) oxide pigments. They are available as bulk industrial products in the required purity. High impurity levels have an unfavorable effect on the hue.

Reduction of Alkali Dichromates. In industrial processes, solid alkali dichromates are reacted with reducing agents such as sulfur or carbon compounds. The reaction is strongly exothermic, and with sulfur proceeds as follows:

$$Na_2Cr_2O_7 + S \rightarrow Cr_2O_3 + Na_2SO_4$$

Sodium sulfate can then easily be separated by washing, because it is water soluble. The use of sulfur was first described in 1820 [218]. ROTH described the use of $K_2Cr_2O_7$ in 1927 [219]. If charcoal is used in place of sulfur, Na_2CO_3 is formed as byproduct [220].

Finely divided sodium dichromate (dihydrate or anhydrous) is mixed homogeneously with sulfur. This mixture is then reacted in a furnace lined with refractory bricks at 750 – 900 °C. An excess of sulfur is used to ensure completion of the reaction. The reaction mass is leached with water to remove water-soluble components such as sodium sulfate. The solid residue is then separated, dried, and ground.

If potassium dichromate is used instead of sodium dichromate, a green pigment with a more bluish hue is obtained.

If it is to be used as a pigment in paints and lacquers, chromium oxide green can be subjected to jet milling (micronization) to obtain the required properties (e.g., gloss).

Reduction of Ammonium Dichromate. Chromium(III) oxide can be obtained by thermal decomposition of ammonium dichromate. Above ca. 200 °C, a highly voluminous product is formed with elimination of nitrogen [221]. The pigment is obtained after addition of alkali salts (e.g., sodium sulfate) and subsequent calcination [222].

In the industrial process, a mixture of ammonium sulfate or chloride and sodium dichromate is calcined [223]:

$$Na_2Cr_2O_7 \cdot 2\,H_2O + (NH_4)_2SO_4 \rightarrow Cr_2O_3 + Na_2SO_4 + 6\,H_2O + N_2$$

The workup is then carried out as described above. A chromium oxide pigment obtained by this process typically contains (wt %):

Cr_2O_3	99.0 – 99.5
SiO_2	0.05 (max.)
Al_2O_3	0.1 (max.)
Fe_2O_3	0.05 (max.)
S	ca. 0.02
Water	ca. 0.3

Chromium oxides with a minimal sulfur content are preferred for metallurgical applications. These are obtained by reacting sodium dichromate with ammonium chloride or sulfate in a deficiency of 10 mol % [224]. Chromium (III) oxides with a low sulfur content can also be obtained by thermal aftertreatment [225]. Thermal decomposition of chromic acid anhydride (CrO_3) yields high-purity chromium(III) oxide [226].

The pigment properties of chromium oxides can be modified by precipitation of hydroxides (e.g., of titanium or aluminum), and subsequent calcining. This treatment changes the color to yellow-green, and decreases the flocculation tendency [227]. Aftertreatment with organic compounds (e.g., alkoxylated alkylsulfonamides) is also used [228].

Other Processes. Other production processes are suggested in the patent literature, but have not so far gained industrial importance. For instance, sodium dichromate can be mixed with heating oil and reacted at 300 °C. The soda formed must be washed out prior to calcining at 800 °C to avoid reoxidation in the alkaline melt [229].

In alkaline solution, sodium chromate can be reduced with sulfur at atmospheric pressure with formation of sodium thiosulfate. After neutralization, more sodium chromate is added to exhaust the reducing capacity of the thiosulfate. The mixture is calcined at 900 – 1070 °C [230].

Another process involves the shock heating of sodium dichromate in a flame at 900 – 1600 °C in the presence of excess hydrogen and chlorine to bind the alkali as sodium chloride [231]. This method is suitable for the preparation of pigment-grade chromium oxide of high purity, with an especially low sulfur content.

Environmental Protection. Since alkali dichromates or chromic acid anhydride are used as starting materials for the production of chromium(III) oxides, occupational health requirements for the handling of hexavalent chromium compounds must be observed [232]. The sulfur dioxide formed on reduction with excess sulfur must be removed from the flue gases according to national regulations, e.g., by oxidation to H_2SO_4.

Process wastewater may contain small amounts of unreacted chromates; recovery is uneconomical. Prior to release into drainage systems, the chromates in these wastewater streams must be reduced (e.g., with SO_2 or $NaHSO_3$) and precipitated as chromium hydroxide [233]. In Germany, for example, the minimum requirements for wastewater in the production of chromium oxide pigments are specified in [234].

3.1.2.3. *Quality Specifications and Analysis*

International, technical specifications for chromium oxide pigments are defined in ISO 4621 (1986), they must have a minimum Cr_2O_3 content of 96 wt %.

Various grades are defined according to their particle fineness as measured by the residue on a 45 µm sieve: grade 1, 0.01 % residue (max.); grade 2, 0.1 % (max.); and grade 3, 0.5 % (max.).

ISO 4621 (1986) also specifies analytical methods. Usually, analysis of chromium and the byproducts is preceded by melting with soda and sodium peroxide. The content of water-soluble or acid-soluble chromium is becoming important from the toxicological and ecological point of view. It is determined according to DIN 53 780 with water, or according to ISO 385 615 with 0.1 mol/L hydrochloric acid.

3.1.2.4. *Storage and Transportation*

Chromium(III) oxide pigments are thermally stable and insoluble in water. They are not classified as hazardous materials and are not subject to international transport regulations. As long as they are kept dry their utility as a pigment is practically unlimited.

3.1.2.5. *Uses*

The use of chromium(III) oxide as a pigment for toys, cosmetics, and in plastics and paints that come in contact with food is permitted in national and international regulations [235-242]. Maximum limits for heavy metals or their soluble fractions are usually a prerequisite. Because pure starting materials are used, these limits are satisfied by most types of chromium oxide.

Chromium oxide is equally important as a colorant and in its other industrial applications. As a pigment, it is used predominantly in the paint and coatings industry for high quality green paints with special requirements, especially for steel constructions (coil coating), facade coatings (emulsion paints), and automotive coatings.

A series of RAL tints (e.g., Nos. 6003, 6006, 6011, 6014, and 6015) can be formulated based on chromium oxide. As mentioned previously, chromium oxide is also an important pigment for the formulation of green camouflage coatings (e.g., RAL 6031-F 9, Natogreen 285, Stanag 2338, and Forestgreen MIL-C-46168 C).

Except for the expensive cobalt green, chromium oxide is the only green pigment that meets the high color stability requirements for building materials based on lime and cement [243]. In plastics, however, chromium oxide green is only of minor importance because of its dull tint.

The industrial significance of chromium oxide is due to its chemical and physical properties. Its high purity makes it suitable as a starting material for the aluminothermic production of very pure chromium metal.

Since the late 1970s chromium oxide has gained significance as a raw material in the refractory industry. The addition of chromium oxide to bricks and refractory concrete based on alumina significantly improves their stability against slag in the production and processing of pig iron. Chromium oxide bricks containing ca. 95 wt % Cr_2O_3 have become important in the production of E-glass fibers (see ⟶ Fibers, 5. Synthetic Inorganic – Chemical Composition and Properties) for lining melting tanks. These linings have substantially improved furnace stability (i.e., prolonged furnace life).

The high hardness of chromium oxide resulting from its crystal structure is exploited in polishing agents for metals and in brake linings. Addition of a small amount of chromium oxide to magnetic materials of audio and video tapes imparts a self- cleaning effect to the sound heads.

3.1.2.6. *Economic Aspects*

Important producers are American Chrome and Chemicals (USA), Bayer (Germany), British Chrome and Chemicals (UK), and Nihon Denko (Japan).

Statistical data on the consumption of chromium oxide have not been published recently. However, it can be assumed that the world capacity in 1996 was about 72 000 t/a; thereof 43 000 t/a in Eastern Europe and the GUS. The consumption as pigments in 1996 is estimated at 28 000 t

3.1.2.7. *Toxicology and Occupational Health*

Toxicological or carcinogenic effects have not been detected in rats receiving up to 5 % chromium(III) oxide in their feed [244] nor in medical studies performed in chemical plants producing chromium(III) oxide and chromium(III) sulfate [245]. The oral LD_{50} for chromium(III) oxide in the rat is > 10 000 mg/kg; it does not irritate the skin or mucous membranes.

Chromium(III) oxide is not included in the MAK list (Germany), the TLV list (USA), or in the list of hazardous occupational materials of the EC [246]. In practice, this means that chromium(III) oxide can be regarded as an inert fine dust with a MAK value of 6 mg/m^3.

3.1.3. ***Mixed Metal Oxide Pigments***

The term mixed metal oxide pigment denotes a pigment that crystallizes in a stable oxide lattice, and in which the color is due to the incorporation of colored cations in this lattice. Such compounds are regarded as solid solutions. The American “Dry Color Manufacturers' Association” has abandoned the term “mixed metal oxide inorganic colored pigments”, it denotes these colorants as “complex inorganic color pigments” [247].

According to V. M. GOLDSCHMITT, two substances with the same basic formula and crystal structure form solid solutions in a concentration range that depends on the degree of similarity of their ionic radii. A large range of solid solutions may be expected if the radius of the larger ion does not exceed that of the smaller by more than 15 % [248].

Solid solutions can also be formed to a limited extent with substances that have a similar formula but a different crystal structure. One of the substances imposes its structure upon the other. In lattices which are stable even if some sites in the unit cell are unoccupied, substances with different formulae can form solid solutions (anomalous mixed crystals). The incorporated ions must be of similar size, but do not need to have the same valency because electroneutrality is ensured by the presence of a compensating valency elsewhere in the lattice. Changes in the relative concentrations in the solid solutions lead to continuous variation of their properties.

In principle, the number of possible mixed metal oxide phases that can be produced from different substituent elements and oxide lattices is extremely large. Systematic investigations have greatly increased the knowledge about mixed metal oxide phases [249].

The only stable oxide lattices that have so far been of value as mixed metal oxide pigments are those with spinel, rutile, and hematite structures. These lattices possess not only good thermal and chemical stability, but also have a high refractive index which is important for good optical pigment properties.

3.1.3.1. *Properties*

Rutile Mixed Metal Oxide Pigments. The rutile (TiO_2) lattice offers considerable scope for variation (see Section Properties) [249]. In this lattice, titanium ions are surrounded by six neighboring oxygen atoms at the corners of a regular, but slightly distorted octahedron. Colored pigments may be obtained by substituting transition-metal ions for the titanium ions [250]. If the colored cation substituent is not tetravalent, another cation of appropriate valency must be substituted into the rutile lattice to maintain an average cation valency of four.

H. H. SCHAUMANN prepared the first mixed-phase rutile pigments by incorporating nickel oxide and antimony oxide into rutile to give a yellow pigment, and cobalt and antimony oxides to give an ocher pigment [251]. Other rutile mixed metal oxide phases were first used as ceramic colorants (e.g., with chromium – tungsten, brown [252]) or for coloring porcelain enamels (e.g., with copper – antimony, lemon yellow; manganese – antimony, dark brown; iron – antimony, gray [253]; and vanadium – antimony, dark gray). In commercial mixed-phase rutile pigments, between 10 and 20 mol % of the titanium ions are replaced by substituent metal ions.

Nickel and chromium mixed-phase rutile pigments are industrially important. When nickel and chromium are substituted into the rutile lattice, higher valency metals (e.g., antimony, niobium, or tungsten) must also be substituted to maintain an average valency of four.

Nickel rutile yellow [8007-18-9], C.I. Pigment Yellow 53:77788, is a light lemon yellow pigment with the approximate composition $(Ti_{0.85}Sb_{0.10}Ni_{0.05})O_2$. Antimony can be replaced by niobium without any appreciable change in color [254].

Chromium rutile yellow pigments [68186-90-3], C.I. Pigment Brown 24:77310, usually contain antimony to balance the valency. Their composition is approximately $(Ti_{0.90}Sb_{0.05}Cr_{0.05})O_2$. Depending on particle size, the color varies from light to medium ocher (buff). Stability towards plastics at high temperature is considerably improved by the incorporation of small quantities of lithium [255] or magnesium [256]. If antimony is replaced by tungsten, the products become darker in color, whereas replacement by niobium leaves the color unchanged.

Spinel Mixed Metal Oxide Pigments. The crystal structure of spinel, $MgAl_2O_4$, is made up of an approximately cubic closely packed array of oxygen ions (Fig. 26). The unit cell contains 32 oxygen ions. Of the 64 possible tetrahedral sites, 8 are occupied by magnesium ions; of the 32 possible octahedral sites, 16 are occupied by aluminum ions.

Figure 26. Structure of spinel showing two octants of the unit cell

Two oxygen ions of neighboring octants are included (dashed circles) to show the arrangement of oxygen around the octahedral sites.

a) Oxygen; b) Cations occupying octahedral sites; c) Cations occupying tetrahedral sites

The inverse spinel structure differs in that one type of cation occupies the tetrahedral and half of the octahedral sites of the spinel lattice, and the other cations occupy the remaining octahedral sites. This is indicated by writing the formula of, for example, zinc titanium spinel as $Zn(TiZn)O_4$. Spinels containing di- and tetravalent cations are mostly of the inverse type. Normal and inverse spinels should be regarded as idealized limiting structures, intermediate forms are often observed in practice. A large range of spinel phases can be formed due to the numerous combinations of cations in the oxidation states 1 – 6, especially from elements of the first transition-metal series. This range is increased if some of the cation sites remain unoccupied. Further details are given in [257].

Many spinel phases have been used as colorants for ceramics and porcelain enamels (⟶ Ceramic Colorants). The most important pigments based on spinel phases used in paints, plastics, and building materials are given in Table 25.

Table 25. Mixed-phase spinel pigments

Trivial name	Formula	CAS registry no.	C.I. name and no.	Color	Crystal structure
Cobalt blue	$CoAl_2O_4$	[1345-16-0]	Pigment Blue 28:77 346	reddish blue	spinel
	$Co(Al,Cr)_2O_4$	[68187-11-1]	Pigment Blue 36:77 343	greenish blue	spinel
Cobalt green	$(Co,Ni,Zn)_2TiO_4$	[68186-85-6]	Pigment Green 50:77 377	green	inverse spinel
Zinc iron brown	$ZnFe_2O_4$	[68187-51-9]	Pigment Yellow 119:77 496	light to medium brown	spinel
Spinel black	$Cu(Cr,Mn)_2O_4$	[68186-91-4]	Pigment Black 28:77 428	black	spinel
	$Cu(Fe,Cr)_2O_4$	[55353-02-1]	Pigment Black 22:77 429		intermediate between normal and inverse spinel

Cobalt Blue. This was formerly known as Thénard's blue, and is a cobalt aluminum spinel. It usually has a deficiency of cobalt (ca. 0.6 – 0.7 mol CoO/mol Al_2O_3) compared with the ideal formula $CoAl_2O_4$. It has a brilliant blue hue with a red tinge. The tetrahedral holes can be filled by incorporating zinc or magnesium ions in the lattice. If chromium is used in place of aluminum, the hue is shifted via neutral blue (molar ratio Al:Cr≈7:3) to a greenish blue (molar ratio Al:Cr≈3:7). Brilliance decreases with increasing chromium content, while the hiding power increases.

Cobalt Green. Incorporation of cobalt in the inverse titanium spinels Mg_2TiO_4 and Zn_2TiO_4 produces blue to green hues. The green color results when cobalt ions occupy the octahedral sites [258]. Both the blue and the green pigments have patent protection [259], and correspond to inverse spinels with the general formula $Mg_aCo_bZn_cTiO_4$ (where $a+b+c = 2$). A brilliant cobalt green is obtained if magnesium is replaced by nickel, giving the approximate stoichiometry $NiCo_{0.5}Zn_{0.5}TiO_4$ [260]. Turquoise spinels are obtained by including lithium, $Li_2(Co,Ni,Zn)Ti_3O_8$ [261].

Zinc Iron Brown. Variation of the zinc to iron ratio in red-brown iron spinel ($ZnFe_2O_4$), or replacement of some of the iron ions by aluminum and titanium ions, gives light to medium brown pigments. Inclusion of a small proportion of lithium ions considerably improves stability towards reducing agents, e.g., when the pigments are used to color plastics [262]. The partial replacement of iron ions by chromium(III) ions yields dark brown products [263].

Spinel Black. Iron – chrome spinels of composition $CuFe_{0.5}Cr_{1.5}O_4$ provide black pigments with good tinting strength. Other commercial black pigments are copper chromites, $CuCr_2O_4$, in which part of the chromium may be replaced by manganese.

Mixed Metal Oxide Pigments with Hematite and Bixbyite Structures. Manganese and chromium can be incorporated in the hematite lattice of α-Fe_2O_3 which has a higher refractive index than rutile. Brown, temperature-resistant iron oxide pigments with the hematite structure are described in Section Synthetic Iron Oxide Pigments, e.g., α-$(Fe,Mn)_2O_3$ [264] and α-$(Fe,Cr)_2O_3$ [265]. The bixbyite lattice of α-Mn_2O_3 can take up > 50 % Fe_2O_3 in solid solution while retaining its structure [266]. Heat-stable black pigments with good tinting strength are obtained.

3.1.3.2. *Production*

The mixed metal oxide pigments are usually produced by reaction of the components in the solid state at 800 – 1400 °C. The reactions proceed more readily if the components are reactive, finely divided, and intimately mixed. The reactants are therefore usually extremely finely divided oxides, hydroxides, carbonates, or nitrates that are mixed in the form of aqueous suspensions. As these raw materials are commercially available with great purity and fineness, coprecipitation of hydroxides or carbonates from aqueous salt solutions is generally not required. Rutile mixed metal oxide phases based on titanium dioxide are prepared from the reactive anatase modification or titanium dioxide hydrolysate, an intermediate in titanium dioxide production.

Wet mixes are usually dried before calcination. Calcination is performed continuously in rotary or tunnel kilns, or batchwise in directly fired drum or box furnaces. The temperature at which the mixed metal oxide pigments are formed can be reduced by adding mineralizing agents [250]. In the case of chromium rutile pigments, addition of magnesium compounds [256] or lithium compounds [255] before calcination improves thermal stability in plastics.

The formation of rutile mixed phases in the system Ti – Ni – Sb – O is described in detail in [267]. When nickel ions are to be included in the pigment and antimony trioxide is used to provide the antimony ions, oxygen must be present to ensure that nickel and antimony occupy the titanium sites in the lattice. If oxygen is excluded, only small amounts of nickel and antimony are taken up in solid solution, and no useful products are formed. The presence of oxidizing agents (e.g., nitrates) is necessary for the production of antimony- containing mixed metal oxide pigments.

After calcination, the products are ground to the desired fineness. Calcined products containing salts are subjected to wet grinding followed by washing, drying, and dry grinding. With salt-free calcination products, washing of the pigments can be omitted. and dry grinding is possible.

When mixed-phase rutile pigments are used in special paint systems, (e.g., stoving or acid-catalyzed lacquers), inorganic surface treatment in an aqueous medium can improve the gloss and flocculation properties. For example, an aqueous pigment suspension is first treated with a surfactant, and then coated with metal hydroxides or oxide hydrates [268].

Chromium rutile pigments with extremely high resistance to flocculation are obtained by applying a double-layer coating of oxides or oxide hydrates formed from tetravalent metals and oxides or oxide hydrates of aluminum [269].

3.1.3.3. *Quality Specifications and Analysis*

There are as yet no national or international (ISO) standards for mixed metal oxide pigments, and none are expected in the foreseeable future. However, the general tests of chemical, physical, and optical properties described in ASTM, DIN, or ISO standards for pigments may be utilized, such as DIN 6174, DIN 55 986, and ISO 787 Part 16 for the optical properties, and ISO 787 Parts 1 – 20 for the physical properties (see also Table 1).

There are no standard methods for the chemical analysis of mixed metal oxide pigments. They are first decomposed (e.g., with peroxide in the case of rutile mixed phases, or soda borax for the spinels) and the appropriate methods are then used to determine the elements.

3.1.3.4. *Storage and Transportation*

Mixed metal oxide pigments are thermally stable, water-insoluble materials. They are not classified as hazardous substances, and are therefore not subject to international transport regulations. When stored under dry conditions their pigment properties do not deteriorate.

3.1.3.5. *Legal Aspects*

Mixed metal oxide pigments are permitted in almost all countries for coloring paints and plastics in contact with foods, or for toy manufacture [270-274]. The legal limits for a number of elements (sometimes for the soluble fraction only) must be observed. Owing to the large number of raw materials and processes used, general purity requirements cannot be specified. Each manufacturer must supply relevant data.

In the EC guidelines for coloring agents for foods [275], cosmetics [276], or pharmaceuticals [277], there are no references to mixed metal oxide pigments, and these are therefore not permitted.

3.1.3.6. *Uses*

The outstanding properties of the mixed metal oxide pigments are their lightfastness and resistance to temperature, chemicals (including acid and alkali), and weathering.

Owing to their high scattering power, their hiding power is much better than that of organic pigments. They are therefore used in combination with organic pigments as base pigments for colored coatings, e.g., for lead-free and chromate-free automobile topcoats (nickel rutile yellow, chromium rutile yellow).

The stability of these pigments makes them suitable for all types of coatings, especially those which have to meet high standards of lightfastness and resistance to weathering or chemicals. They are especially suitable for baking enamels, coil coatings, powder coatings, as well as for coloring plastics, masonry coatings based on resin emulsions or waterglass, and building materials.

A very important use for rutile yellow is in coil coating of aluminum and steel, especially in the building industry, but also for containers, vehicles, and machinery.

Rutile yellow is used in rigid poly(vinyl chloride) for outdoor use (USA: vinyl siding); cobalt blue and cobalt green are employed to color high-density polyethylene (bottle crates). Rutile yellow is being used increasingly in engineering plastics to replace cadmium pigments, which have unfavorable toxicological and ecological properties. Rutile yellow pigments can be used cheaply and advantageously for this purpose instead of a combination of titanium dioxide and expensive organic colorants. Nickel and chromium rutiles can replace cadmium yellow as toning pigments. Rutile yellow pigments can be safely used in all plastics. However, chromium rutiles are only resistant up to 280 °C, though this disadvantage can be overcome by lattice stabilization (see Rutile Mixed Metal Oxide Pigments.).

Trade names of some mixed metal oxide pigments include Heucodur (Dr. H. Heubach, Germany); Irgacolor (Ciba-Geigy, Switzerland); Lichtechtpigmente (Bayer, Germany); Sicotan-Gelb, Sicopal-Blau (BASF, Germany); Tipaque Yellow (Ishihara, Japan); Kerafast (Blythe Colours, UK); and Meteor Colors (Engelhard, USA). Ferro (USA), another important producer of these pigments, does not use a specific trade name.

3.1.3.7. *Economic Aspects*

No statistical information concerning the use of mixed metal oxide pigments has been published. However, it is estimated that world consumption, excluding the former Eastern bloc and China, was ca. 15 000 t in 1996. There is no definite information available on whether or not production of mixed metal oxide pigments takes place in the former Eastern bloc countries or China.

3.1.3.8. *Toxicology and Occupational Health*

Mixed metal oxide pigments contain one or more heavy metals, whose oxides can have toxicological effects. However, these heavy metals in the mixed metal oxide phase occur as different compounds, even if the respective oxides are used as raw materials for pigment production. They have an extremely low solubility in water and dilute acids. Toxicological investigations with nickel and chromium rutile yellow have shown that, even at high dose rates (up to 1 % in animal feeds), these pigments are not toxic or biologically available [278]. Cobalt spinels, unlike cobalt oxide, do not have carcinogenic properties [279]. Also, the waste disposal of paints and plastics colored with mixed metal oxide pigments is regarded as safe [280].

Only nickel rutile yellow has so far been included in the MAK list in Class II b, edition 1996; toxicological data available for other pigments are inadequate. The mixed metal oxide pigments are not included in the EC guidelines for hazardous materials (67/548/EC) or in the TLV list for 1990/1995.

3.2. Cadmium Pigments

Among the inorganic pigments, cadmium pigments have particularly brilliant red and yellow colors, as well as a high durability. All cadmium pigments are based on cadmium sulfide and crystallize with a hexagonal wurtzite lattice (Fig. 27). The sulfur atoms have a hexagonal, tightly packed arrangement, in which the cadmium atoms occupy half of the tetrahedral holes. In this wurtzite lattice the cations and anions can be replaced within certain limits by chemically similar elements; nevertheless, the only substitutions which are used in practice are zinc and mercury for the cations, and selenium for the anions.

Figure 27. Crystal lattice of cadmium pigments (wurtzite structure)

a) Sulfur (selenium); b) Cadmium (zinc, mercury)

The use of zinc yields greenish yellow pigments due to the smaller lattice constants; mercury and selenium lead to expansion of the lattice. With an increasing content of selenium, or especially mercury, the shades of the pigments change to orange, red, and ultimately to deep red (bordeaux). The brilliant colors of cadmium pigments are primarily due to their almost ideal reflectance curves with a steep ascent (Fig. 28).

Figure 28. Reflectance curves of cadmium pigments (pigment volume concentration 10 %)

a) Cadmium yellow; b) Cadmium golden yellow; c) Cadmium red (bordeaux)

3.2.1. *Cadmium Sulfide*

Cadmium sulfide [1306-23-6], CdS, M_r 144.48, occurs as greenockite or cadmium blende in several natural deposits, which are, however, of no importance as pigments. The mineral crystallizes hexagonally in the wurtzite lattice (α-form).

When hydrogen sulfide is passed into cadmium salt solutions, cadmium sulfide is formed as a yellow precipitate with a zinc blende structure (cubic, β-form). The β-form can be converted into the α-form (e.g., by heating). α- Cadmium sulfide shows photoconductivity due to defects in the crystal lattice (usage in photovoltaic cells) [281]. The solubility in water at 25 °C is 1.46×10^{-10} mol/L [282]. Cadmium sulfide forms the basis for all cadmium pigments.

3.2.2. *Cadmium Yellow*

Cadmium yellow consists of pure cadmium sulfide (golden yellow color) or mixed crystals of zinc and cadmium sulfide [8048-07-5], (Cd, Zn)S, in which up to one-third of the cadmium can be replaced by zinc. The density of this pigment is 4.5 – 4.8 g/cm^3 and its refractive index is 2.4 – 2.5. The prevalent particle size is approx. 0.2 µm with cubic to spheroidal habits. Cadmium yellow is practically insoluble in water and alkali, and of low solubility in dilute mineral acid. It dissolves in concentrated mineral acid with generation of hydrogen sulfide.

Production. The raw material for the production of cadmium yellow pigments is high-purity cadmium metal (99.99 %), cadmium oxide, or cadmium carbonate. If the metal is used it is first dissolved in mineral acid. A zinc salt is then added to the solution in an amount that depends on the desired shade. This is followed by addition of sodium sulfide solution. An extremely finely divided cadmium sulfide or cadmium zinc sulfide precipitate is formed which does not possess any pigment properties. This intermediate product can also be obtained by mixing the cadmium or cadmium – zinc salt solution with sodium carbonate solution. An alkaline cadmium carbonate or cadmium zinc carbonate precipitate is formed which reacts in suspension with added sodium sulfide solution.

The crude precipitated cadmium yellow is washed and then calcined at approx. 600 °C, at which temperature the cubic crystal form changes to the hexagonal form. This process determines the particle size distribution, which is essential for the pigment properties.

If the starting material is cadmium oxide or cadmium carbonate, it is mixed with sulfur and calcined at approx. 600 °C. After calcination, the pigment product is washed with dilute mineral acid to remove any remaining soluble salts, dried, and ground.

3.2.3. *Cadmium Sulfoselenide (Cadmium Red)*

Pure cadmium selenide [1306-24-7], CdSe, is brownish black and has no pigment properties. Like cadmium sulfide, it is dimorphous and occurs in hexagonal and cubic modifications. Cadmium selenide is insoluble in dilute acid. It readily liberates hydrogen selenide in concentrated hydrochloric acid. It dissolves completely in fuming nitric acid, the Se^{2-} ions being converted to SeO_4^{2-} ions. Cadmium selenide is an *n*-type semiconductor.

Cadmium red consists of cadmium sulfoselenide [12656-57-4], [58339-34-7], Cd(S,Se), and is formed when sulfur is replaced by selenium in the cadmium sulfide lattice. With increasing selenium content, the color changes to orange, red, and finally dark red. The density of these pigments increases correspondingly from 4.6 to 5.6 g/cm^3 and the refractive index from 2.5 to 2.8. The crystals have cubic or spheroidal habits, and the prevalent particle size is 0.3 – 0.4 µm.

Production. Cadmium red pigments are produced in a similar way to the cadmium yellow pigments. The cadmium salt solution is prepared by dissolving the metal in mineral acid and then sodium sulfide is added. A certain amount of selenium powder is dissolved in the sodium sulfide solution to obtain the desired color shade. In an alternative procedure, the cadmium solution is mixed with sodium carbonate solution to precipitate cadmium carbonate, which is reacted with the selenium- containing sodium sulfide solution.

The cadmium red pigment intermediate is obtained as a precipitate and is filtered off, washed, and calcined at approx. 600 °C. As with cadmium yellow, calcination yields the red pigment and determines the particle size, particle size distribution, and color shade. Analogously to the cadmium yellow process, cadmium red can be produced by direct reaction of cadmium oxide or cadmium carbonate with sulfur and the required amount of selenium at ca. 600 °C.

Products in which selenium is totally or partially replaced by tellurium [283], [284] have not had any commercial application owing to their poor coloristic properties.

3.2.4. *Cadmium Mercury Sulfide (Cadmium Cinnabar)*

The cadmium in the wurtzite lattice of cadmium sulfide can be replaced by divalent mercury to give cadmium mercury sulfide (cadmium cinnabar). As the quantity of mercury increases, the lattice expands, and the color deepens from yellow to orange and finally dark red. The coloring properties of cadmium cinnabar resemble those of the selenium- containing cadmium red pigments. Use of these mercury- containing pigments can be justified for economic reasons. However, their use is no longer justifiable from the ecological point of view because adequate nontoxic substitutes are available.

3.2.5. *Properties and Uses*

Cadmium pigments are mainly used to color plastics. They have brilliant, pure shades (yellow, orange, red, and bordeaux), good hiding power, and moderate tinting strength.

Their process-relevant properties are determined by their high thermal stability and chemical resistance to aggressive additives or to molten plastics that have a reducing action (e.g., polyamides). Other advantages for use in plastics are good lightfastness, weather resistance, and migration resistance. The cadmium pigments also protect polyolefins against aging by absorbing UV light. Premature embrittlement is prevented and the polymer can be recycled [285].

A very useful feature of plastics colored with cadmium pigments is the dimensional stability of injection moldings with a large surface area. This combination of properties is not matched by any other class of colorant.

For economic reasons, cadmium pigments are no longer used for coloring plastics where the pigment property requirements are less stringent. In poly(vinyl chloride) and to a large extent in low-density polyethylene, they have been replaced by less expensive inorganic and organic pigments.

For ecological reasons, cadmium pigments are increasingly being replaced in plastics for which high demands are made on the colorants, sometimes with concessions as regards product quality. Plastics processed at high temperature are now colored with high-quality organic pigments (e.g., perylene, quinacridone, and high-quality azo pigments), often in combination with inorganic pigments, which provide the required covering power. With increasing processing temperature and for outdoor use, the amount of substitution product is lower. Some compromises in processability and product quality, including shade and brilliance have to be accepted.

A further use of cadmium pigments is in paints and coatings (powder paints, silicone resins, and automotive topcoats), but this is declining.

Cadmium pigments are irreplaceable for coloring enamels, ceramic glazes (⟶ Ceramic Colorants), and glass to the highest brilliance. Brilliant transparent glasses are obtained by adding a small amount of cadmium red, while 10 % cadmium red with a cadmium oxide stabilizer produces dark decorative glasses. Other areas of application are ceramics (wall and floor tiles, household and decorative ceramic ware). Very small amounts of cadmium pigments are used for artists' colors. The terms cadmium yellow and cadmium red have become synonyms for very brilliant red and yellow shades.

Cadmium pigments, especially cadmium red, are very sensitive to intensive grinding, which causes loss of brilliance due to an increase in the number of irregular lattice defects. A brilliant red shade may become a dirty brownish red.

The cadmium pigments are lightfast but, like all sulfide pigments, are slowly oxidized to soluble sulfates by UV light, air, and water. This photooxidation is more pronounced with cadmium yellow than with cadmium red and can still be detected in the powder pigment, which normally contains 0.1 % moisture.

Regulations Regarding Foods. The cadmium pigments fulfil the legal requirements of the EU countries for colorants used in plastics which come in contact with food.

Except for polyamide 6, only microgram quantities of cadmium can be extracted from colored plastics into simulants [286], [287]. Cadmium pigments are no longer listed in the French positive list.

To prevent even minimal intake of cadmium, the European Commission has passed a resolution which states that cadmium pigments should only be used for these purposes if adequate substitutes are not available [288].

The use of cadmium pigments in ceramics is controlled in the EU Guideline No. 84/500/EC. International standards [Part I (Methods) and Part II (Limit Values)] are as follows: ceramic surfaces ISO 6486, enamel ISO 4531, and glass ISO 7086.

3.2.6. *Quality Specifications*

The quality requirements and conditions for the supply of cadmium pigments given in ISO 4620 have lost their significance in practice. According to this standard, cadmium pigments must be free from organic colorants, inorganic colored pigments, and other additives. The acid-soluble components (0.1 mol/L HCl) should not exceed 0.2 % Cd (determined according to ISO 4620 and ISO 3856/4); in practice, they are usually < 0.01 % Cd.

Cadmium pigments are sold as homogeneous powders and as preparations mixed with barium sulfate to give the required tinting strength. To reduce the risk of inhalation (see Section Toxicology and Environmental Protection), they are supplied as low-dust powders and fine granules.

In dust-free and dispersed form, they are supplied as concentrated plastic granules (masterbatch pellets), as concentrated pastes, and as liquid colors. These products are added at different stages in the processing of plastics.

3.2.7. *Economic Aspects*

The output of cadmium pigments in the industrialized countries in 1995 was approximately 3000 t, of which about 2000 t was produced in Europe and 500 t in the United States. Consumption is distributed approximately as follows: plastics 90 %, ceramics 8 %, and others 2 %.

Manufacturers and *trade names* of cadmium pigments include Cerdec AG, Frankfurt, Germany; Orkem, Narbonne, France (Langdopec Pigments); J. M. Brown, Stoke-on-Trent, UK ; Cookson-Matthey, Kidsgrove, UK ; Ferro Corporation, Color Division, Cleveland, USA ; and Harshaw Chemical Co., Cleveland, USA.

3.2.8. *Toxicology and Environmental Protection*

Production. Since soluble cadmium compounds have a toxic effect on humans and the environment, all wastewater originating from the production of cadmium pigments must be treated to remove cadmium. This is carried out by methods outlined elsewhere (⟶ Cadmium and Cadmium Compounds – Waste Water). In the EC, the following limits for the pigment production must be observed: 0.2 mg Cd/L in wastewater and 0.3 kg Cd per tonne of used cadmium compounds, calculated as metal [289].

The exhaust air from the production plants and the ventilation equipment must be cleaned. Tubular filters and, more recently, absolute filters have been used to remove cadmium compounds in dust form. With these high-performance filters, it is possible to comply with the limits specified in Germany (0.2 mg Cd air, 1 g Cd/h, emission limit; 5 µg Cd m^{-2} d^{-1}, immission limit). During pigment production, occupational hygiene and safety measures for toxic materials must be observed. Exposure to cadmium can be determined by measurements of the workplace concentration and by examination of the cadmium levels in blood and urine. In Germany, the following maximum BAT values are permitted in the workplace: 15 µg Cd per liter urine and 1.5 µg Cd per 100 mL blood. The TRK value for cadmium pigments is 0.015 mg/m^3. In the United States, the TLV value for cadmium and its compounds is 0.01 mg Cd/m^3. The OSHA Cadmium Standard has a PEL value of 0.005 mg Cd/m^3.

Toxicity. The toxicity of soluble cadmium compounds is described elsewhere (⟶ Cadmium and Cadmium Compounds – Toxicology and Occupational Health). Cadmium pigments are cadmium compounds of low solubility. However, in dilute hydrochloric acid (concentration equivalent to stomach acid) small quantities of cadmium are dissolved, and long-term oral intake of cadmium pigments can lead to accumulation in the human body. On inhalation of subchronic amounts of cadmium pigments, a small proportion of cadmium is biologically available [290], [291]. Cadmium pigments have no acute toxic effect (oral LD_{50}, rat, > 10 g/kg). The pigments do not have any adverse effects on the skin and mucous membranes.

Genotoxic Effects and Carcinogenicity. Tests for DNA damage [292] and cell transformation caused by crystalline cadmium sulfide were positive [293]. Cadmium sulfide also proved to be carcinogenic by intraperitoneal and after intratracheal administration [294]. The significance of such animal studies is being controversially discussed by toxicologists.

Long-term animal feeding studies with various cadmium compounds show no carcinogenic risks. However, in inhalation studies with cadmium oxide, cadmium chloride, cadmium sulfate, and cadmium sulfide in rats, mice, and hamsters, all four compounds produced a significantly increased incidence of lung cancer in rats [295]. The results for mice were inconclusive, and no carcinogenicity was observed in hamsters [296]. Reinvestigation of the inhalation studies has shown that the test was not applicable to cadmium sulfide. The inhaled liquid cadmium sulfide suspension contained up to 40 % cadmium sulfate formed by light-induced oxidation.

In 1989 the German Senate Commission for the Assessment of Hazardous Substances classified cadmium and its compounds (including cadmium sulfide) among those substances whose carcinogenicity has been clearly proven in animal studies under conditions comparable to potential human exposure in the workplace (Group III A 2). According to the MAK classification, cadmium pigments and preparations that contain cadmium pigments in concentrations above 0.1 % must therefore be regarded as carcinogenic if they occur in an inhalable form. In the United States, the National Toxicology Program (NTP) has shown that cadmium and various cadmium compounds (including cadmium sulfide) have a carcinogenic effect in animal experiments. In 1991 the EU reported the above-mentioned error in the inhalation studies and classified cadmium sulfide in the EU Cancer List in Category III (suspected carcinogen). In the EU pure cadmium sulfide is labelled with the symbol T (Toxic) and the R phrases 22–40–48/23/25 (harmful if swallowed; possible risks of irreversible effects; toxic: danger of serious damage to health by prolonged exposure through inhalation and if swallowed). Cadmium compounds must be labelled with the symbol Xn (Harmful) and the Risk Phrases 20/21/22 (harmful by inhalation, in contact with skin, and if swallowed). The cadmium pigments (cadmium zinc sulfide and cadmium sulfide selenide) are exempted from labelling. The cadmium pigments are slightly soluble in dilute acids, and the dissolved cadmium is bioavailable. Therefore, some cadmium pigment producers label their cadmium zinc sulfide and cadmium sulfide selenide pigments like the cadmium compounds.

Limitations of Use. In 1981 Sweden prohibited the use of cadmium pigments (with some exceptions) for ecological reasons. In 1987 Switzerland prohibited the use of cadmium pigments in plastics. Exceptions are possible if valid reasons can be given.

In 1991 the EC passed a directive to prohibit the use of cadmium pigments as colorants for certain plastics that can easily be colored with other pigments [297]. A transition period was granted for further series of plastics, which may not be colored with cadmium pigments since January 1, 1996. The maximum cadmium content in plastics is limited to 0.01 %, a range which includes typical industrial impurity levels but in which technically convenient coloring is not practicable. Use in coating media is also prohibited since January 1, 1996. Use in artists' colors and ceramic products (including coatings used for ceramic products) is still permitted.

The directive determined that the prohibited lists shall be revised and possibly extended after five years. Revision is due in 1997, and it is expected that the limit value of 0.01 % will be lowered to 0.005 % Cd.

In 1989 the CONEG Model (Coalition of North-Eastern Governors) was passed by 14 U.S. States to reduce the environmental pollution by environmentally relevant heavy metals. They decided to limit the total content of the environmentally relevant heavy metals lead, cadmium, mercury, and hexavalent chromium. Since then, the other U.S. States have accepted the model. In the United States, the total content of the four elements must not exceed 100 ppm in packaging since 1994.

These four heavy metals have been included in the EU directive for packaging and packaging waste (94/62/EEC). The limitations on certain heavy metals becomes effective in 1998. The total content of the four elements will be reduced in three steps:

From July 1, 1998 600 ppm
From July 1, 1999 250 ppm
From July 1, 2001 100 ppm

Furthermore, production, handling, or putting into circulation of packaging colored with cadmium pigments will no longer be permitted in the EU. For cadmium-containing returnable crates in circulation, an exception rule passed in 1997.

3.3. Bismuth Pigments

Bismuth- containing special-effect pigments based on platelet-shaped crystals of bismuth oxide chloride (bismuth oxychloride, BiOCl) have been known for a long time (see Section Bismuth Oxychloride). More recently, greenish yellow pigments based on bismuth orthovanadate [14059-33-7], $BiVO_4$, M_r 324, have attracted increasing interest.

They represent a new class of pigments with interesting coloristic properties, extending the familiar range of yellow inorganic pigments (iron yellow, chrome yellow, cadmium yellow, nickel titanium yellow, and chromium titanium yellow).In particular they are able to substitute the greenish yellow shades of the lead chromate and cadmium sulfide pigments.

Historical Aspects. Bismuth vanadate occurs naturally as the brown mineral pucherite (orthorhombic), as clinobisvanite (monoclinic) and as deyerite (tetragonal). Its synthesis was first reported in 1924 in a pharmaceutical patent [298]. The development of pigments based on $BiVO_4$ began in the mid-1970s. In 1976, Du Pont described the preparation and properties of "brilliant primrose yellow" monoclinic bismuth vanadate [299]. Montedison developed numerous pigment combinations based on $BiVO_4$ [300]. Pigments containing other phases besides $BiVO_4$, e. g. Bi_2XO_6 (X= Mo or W), have been reported by BASF [301] and led to the first commercial product (trade name Sicopal Yellow L 1110). Since then Bayer [302], Ciba-Geigy [303], BASF [304] and others have published further methods for the manufacture of pigments based on $BiVO_4$. Pigments for use in paints and plastics are now commercially available from the following suppliers: BASF, Ciba-Geigy, Bayer, Capelle, Bruchsaler Farbenfabrik, and Heubach. Recently, BASF introduced a new reddish yellow bismuth vanadate pigment on the market (trade name Sicopal Yellow L 1600).

3.3.1. *Properties*

Most commercial bismuth vanadate pigments are now based on pure bismuth vanadate with monoclinic or tetragonal structure, though there are still pigments based on the two-phase system bismuth vanadate molybdate, $4\ BiVO_4 \cdot 3\ Bi_2MoO_6$. The pure bismuth vanadate pigments show a higher chroma than the two-phase systems. In the following, the physical and coloristic properties of a pure bismuth vanadate pigment are given (Sicopal Yellow L1100, BASF):

Density	6.1 g/cm^3
Refractive index *n*	2.45
Specific surface area (BET)	13 m^2/g
Oil absorption	33 g/100 g pigment
Composition:	
Bi	64.51 wt %
V	15.73 wt %
O	19.76 wt %

Bismuth vanadate, C.I. Pigment Yellow 184, is a pigment with a greenish yellow color, having high tinting strength, high chroma, and very good hiding power. When compared with other yellow inorganic pigments, it most closely resembles cadmium yellow and chrome yellow in its coloristic properties (Fig. 29). Bismuth vanadate shows a sharp increase in reflectance at 450 nm and considerably higher chroma than iron yellow or nickel titanium yellow. It has very good weather resistance both in full shade and in combination with TiO_2. Pigment properties follow:

Hue angle H° (HGD, hue grade; CIELAB)	93.7
Chroma *C*ab* (CIELAB)	95.5
Hiding power over black/white (42.5 wt % in dry film)	ca. 70 µm
Weather resistance (DIN 54 002)	
Full shade	4 – 5
Mixed with TiO_2, 1 : 10	4 – 5
Chemical resistance in cross-linked paint films	
Acid	5 (2 % HCl)
Alkali	5 (2 % NaOH)
Heat stability	> 200 °C

Figure 29. Reflectance curves of yellow pigments

3.3.2. *Production*

The production process for bismuth vanadate pigments consists usually of a precipitation reaction followed by a calcination step. The calcination step varies from producer to producer and may even be omitted, depending on the precipitation process and the desired product properties.

$$\underset{\text{in } HNO_3 \text{ solution}}{Bi(NO_3)_3 + NaVO_3 + Na_2MoO_4} \xrightarrow{NaOH} \underset{\text{Gel particle}}{2\ Bi_2O_3 \cdot V_2O_5 \cdot MoO_3 \cdot x\ H_2O} + NaNO_3 \qquad (4)$$

$$\underset{\text{Gel particles}}{2\ Bi_2O_3 \cdot V_2O_5 \cdot MoO_3 \cdot x\ H_2O} \xrightarrow{600\,^\circ C} \underset{\text{Polycrystalline particles}}{BiVO_4 \cdot Bi_2MoO_6} + H_2O \qquad (5)$$

In this process a fine precipitate is first formed by adding an alkaline solution of sodium or ammonium vanadate to an acidic bismuth nitrate solution in the presence of a considerable amount of phosphate, or in the inverse process by adding the bismuth nitrate solution to a sodium or ammonium vanadate solution (Fig. 30). Thereafter, the pH is set between 5 and 8 with sodium hydroxide and the precipitate crystallizes to monoclinic or tetragonal bismuth orthovanadate, usually by heating to reflux. After crystallization the pigment is often coated with calcium or zinc phosphate or aluminum oxide to improve the lightfastness and weather resistance. The final step is usually calcination followed by wet milling and spray drying (Fig. 31). The spray drying process produces a finely granulated, dust-free pigment. For use in plastics the pigment is additionally coated with silica and other components to increase its heat stability in certain polymers, e.g. polyamide, up to 320°C.

Figure 31. Flow diagram for the production of bismuth vanadate pigment

a) Reaction vessel; b) Filter; c) Dryer; d) Furnace treatment

3.3.3. *Uses*

Bismuth vanadate pigments are used in the manufacture of lead-free, weather resistant, brilliant yellow colors for automotive finishes and industrial paints. They are suitable for the pigmentation of solvent-containing paints, water-based paints, powder coatings, and coil-coating systems. They can be mixed with other pigments to produce brilliant colors in the orange, red and green regions, such as the German standard colors RAL 1021, 1028, 2004, 3020, 6018, and 6029. Various producers have developed bismuth vanadate pigments for use in plastics, especially polyethylene and technical plastics. The annual production of bismuth vanadate pigments is ca. 500 t. In the near future an increasing market volume of 1000 to 2000 t/a is expected.

3.3.4. *Toxicology*

Bismuth vanadate pigments do not exhibit acute toxicity upon inhalative or oral incorporation. They show chronic toxicity on inhalation due to the vanadium content. The NOEL for rats is 0.1 mg/m^3 (exposure: 3 months, 6 h/d, 5 d/week). The critical factor for the inhalation toxicity is the true amount of pigment in the lungs, and not just the concentration in air. Because of the high density of the pigment and because the supply form is a fine granulate, the risk of inhalation is very low. Therefore the dust-free pigments can be handled under the usual hygienic working conditions [305].

3.4. Chromate Pigments

The most important chromate pigments include the lead chromate (chrome yellow) and lead molybdate pigments (molybdate orange and molybdate red) whose colors range from light lemon yellow to reds with a blue hue. Chrome yellow, molybdate orange, and molybdate red are used in the production of paints, coatings, and plastics, and are characterized by brilliant hues, good tinting strength, and good hiding power. Special treatment of the pigments has allowed continual improvement of their resistance to light, weathering, chemicals, and temperature.

The chromate pigments are also combined with blue pigments (e.g., iron blue or phthalocyanine blue) to obtain high-quality chrome green and fast chrome green pigments. Molybdate orange and molybdate red pigments are often combined with red organic pigments, giving a considerable extension of the color range.

Lead chromates, lead molybdates, chrome greens, and fast chrome greens are supplied as pigment powders, low-dust or dust-free preparations, or as pastes. For standard specifications, see Table 1.

The anticorrosive pigments zinc chromate, zinc tetraoxychromate, and strontium chromate are described in Section Chromate Pigments

3.4.1. *Chrome Yellow*

The chrome yellow pigments [1344-37-2], C.I. Pigment Yellow 34:77600 and 77603, are pure lead chromate or mixed-phase pigments with the general formula $Pb(Cr,S)O_4$ [306] (refractive index 2.3 – 2.65, density ca. 6 g/cm^3). Chrome yellow is insoluble in water. Solubility in acids and alkalis and discoloration by hydrogen sulfide and sulfur dioxide can be reduced to a minimum by precipitating inert metal oxides on the pigment particles.

Both lead chromate and lead sulfochromate (the latter is a mixed-phase pigment) can be orthorhombic or monoclinic; the monoclinic structure is the more stable [307]. The greenish yellow orthorhombic modification of lead chromate is metastable at room temperature, and is readily transformed to the monoclinic modification under certain conditions (e.g., concentration, pH, temperature). The latter modification occurs naturally as crocoite.

Partial replacement of chromate by sulfate in the mixed-phase crystals causes a gradual reduction of tinting strength and hiding power, but allows production of the important chrome yellows with a greenish yellow hue.

Production. In large-scale production, lead or lead oxide is reacted with nitric acid to give lead nitrate solutions, which are then mixed with sodium dichromate solution. If the precipitation solutions contain sulfate, lead sulfochromate is formed as a mixed-phase pigment. After stabilization the pigment is filtered off, washed until free of electrolyte, dried, and ground.

The color of the pigment depends on the ratio of the precipitating components and other factors during and after precipitation (e.g., concentration, pH, temperature, and time). According to WAGNER [308], the precipitated crystals are orthorhombic, but change very readily to the monoclinic form on standing; higher temperatures accelerate this conversion. Almost isometric particles that do not show any dichroism can be obtained by appropriate control of the process conditions. Needle-shaped monoclinic crystals should be avoided because they lead to disadvantages such as low bulk density, high oil absorption, and iridescence in the coating film.

Unstabilized chrome yellow pigments have poor lightfastness, and darken due to redox reactions. Further developments have led to improvements in the fastness properties of chrome yellow pigments, especially toward sulfur dioxide and temperature. This has been achieved by coating the pigment particles with compounds of titanium, cerium, aluminum, antimony, and silicon [309-317].

Carefully controlled precipitation and stabilization provide chrome yellow pigments with exceptional fastness to light and weathering, and very high resistance to chemical attack and temperature, enabling them to be used in a wide field of applications. The following qualities are commercially available:

1. Unstabilized chrome yellows (limited importance)
2. Stabilized chrome yellows with high color brilliance, stable to light and weathering
3. Highly stabilized chrome yellow pigments
   - very stable to light and weathering
   - very stable to light and weathering, and resistant to sulfur dioxide
   - very stable to high temperature, light, and weathering
   - very stable to high temperature, sulfur dioxide, light, and weathering
4. Low-dust products (pastes or powders)

Lightfast chrome yellow pigments that are coated with metal oxides (e.g., of aluminum, titanium, manganese) are produced by Du Pont [310].

A chrome yellow that is coated with large amounts of silicate and alumina and which shows improved stability to temperature, light, and chemicals is also produced by Du Pont [311].

Bayer describes pigments containing lead chromate stabilized in aqueous slurry with silicate- containing solutions and antimony(III), tin(II), or zinc compounds [312].

ICI produces light- and weatherfast chrome yellow pigments stabilized with antimony compounds and silicates in the presence of polyhydric alcohols and hydroxyalkylamines [313].

Ten Horn describes a process for the production of lead sulfochromate containing at least 50 % lead chromate [314]. This has a low acid-soluble lead content (< 5 % expressed as PbO, by BS 3900, Part B3, 1965).

BASF produces temperature-stable lead chromate pigments with a silicate coating obtained by hydrolysis of magnesium silicofluoride [315]

Heubach has developed a process for the alternate precipitation of metal oxides and silicates [316], [317]. A homogenizer is used to disperse the pigment particles during stabilization. Products obtained have a very good temperature resistance and very low lead solubility in acid (< 1 % Pb by DIN 55 770, 1986 or DIN/ISO 6713, 1985).

Continuous processes for the production of chromate pigments have been developed in the United States and Hungary [318], [319].

Uses. Chrome yellow pigments are mainly used for paints, coil coatings, and plastics. They have a low binder demand and good dispersibility, hiding power, tinting strength, gloss, and gloss stability. Chrome yellows are used in a wide range of applications not only for economic reasons, but also on account of their valuable pigment properties. They are important base pigments for yellow colors in the production of automotive and industrial paints.

Chrome yellow pigments stabilized with a large amount of silicate play a major role in the production of colored plastics (e.g., PVC, polyethylene, or polyesters) with high temperature resistance. Incorporation into plastics also improves their chemical resistance to alkali, acid, sulfur dioxide, and hydrogen sulfide.

Chrome green and fast chrome green mixed pigments are produced by combining chrome yellow with iron blue or phthalocyanine blue (see Section Chrome Green and Fast Chrome Green).

World production of chrome yellow in 1996 was 37 000 t.

3.4.2. *Molybdate Red and Molybdate Orange*

Molybdate red and molybdate orange [12656-85-8], C.I. Pigment Red 104:77605, are mixed-phase pigments with the general formula $Pb(Cr,Mo,S)O_4$ [306]. Most commercial products have a MoO_3 content of 4 – 6 % (refractive index 2.3 – 2.65, density 5.4 – 6.3 g/cm^3). Their hue depends on the proportion of molybdate, crystal form,

and particle size.

Pure tetragonal lead molybdate, which is colorless, forms orange to red tetragonal mixed-phase pigments with lead sulfochromate. The composition of molybdate red and molybdate orange pigments can be varied to give the required coloristic properties; commercial products usually contain ca. 10 % lead molybdate. Lead molybdate pigments have a thermodynamically unstable tetragonal crystal modification that can be transformed into the undesirable stable yellow modification merely by dispersing [320]. This is especially true of the bluish varieties of molybdate red which have larger particles whose color can be changed to yellow by shear forces. The tetragonal modification of the lead molybdate pigments must therefore be stabilized after precipitation [321], [322].

The fastness properties of the molybdate orange and molybdate red pigments are comparable with those of the chrome yellows. As with the chrome yellows, the pigment particles can be coated with metal oxides, metal phosphates, silicates, etc., to give stabilized pigments with high color brilliance and good fastness properties, as well as highly stabilized grades with very good resistance to light, weathering, sulfur dioxide, and temperature, and with a very low content of acid-soluble lead (DIN 55 770, 1986 or DIN/ ISO 6713, 1985).

The colors of lead molybdate pigments vary from red with a yellow hue to red with a blue hue. Since chrome orange is no longer available (see Section Chrome Orange), molybdate orange has become much more important.

Production. In the Sherwin – Williams process, a lead nitrate solution is reacted with a solution of sodium dichromate, ammonium molybdate, and sulfuric acid [323]. Instead of ammonium molybdate, the corresponding tungsten salt can be used, giving a pigment based on lead tungstate. The pigment is stabilized by adding sodium silicate (25 % SiO_2) and aluminum sulfate ($Al_2(SO_4)_3 \cdot 18\ H_2O$) to the suspension, which is then neutralized with sodium hydroxide or sodium carbonate. The pigment is filtered off, washed until free of electrolyte, dried, and ground. Treatment with silicate increases the oil absorption; it also improves light fastness and working properties.

In the Bayer process molybdate red is formed from lead nitrate, potassium chromate, sodium sulfate, and ammonium molybdate [312]. The pigment is then stabilized by adding water glass (28 % SiO_2, 8.3 % Na_2O) to the suspension with stirring, followed by solid antimony trifluoride, stirring for 10 min, and further addition of water glass. The pH is adjusted to 7 with dilute sulfuric acid and the pigment is filtered off, washed free of electrolyte, dried, and ground.

To give the lead molybdate pigments very good stability to light, weathering, chemical attack, and temperature, the same methods are used as those for the stabilization of chrome yellow pigments (see Section Chrome Yellow) [309-317].

Uses. Molybdate orange and molybdate red are mainly used in paints, coil coatings, and for coloring plastics (e.g., polyethylene, polyesters, polystyrene). The temperature-stable grades are the most suitable for coil coatings and plastics.

Molybdate orange and molybdate red have a low binder demand; good dispersibility, hiding power, and tinting strength; and very high lightfastness and weather resistance. Stabilization (see “Production”) also gives high-grade pigments with good resistance to sulfur dioxide and high temperature.

Like the chrome yellows, the molybdate reds are used to produce mixed pigments. Combinations with organic red pigments give a considerably extended color range. Such combinations have very good stability properties because the lightfastness and weather resistance of many organic red pigments are not adversely affected by molybdate pigments.

Total world production of molybdate orange and molybdate red in 1996 was 13 000 t.

3.4.3. *Chrome Orange*

Chrome orange [1344-38-3], C.I. Pigment Orange 21:77601, is a basic lead chromate with the composition $PbCrO_4 \cdot PbO$ but is no longer of technical or economic importance.

This product was obtained by precipitating lead salts with alkali chromates in the alkaline pH range. By controlling the pH and temperature, the particle size and thus the hue could be varied between orange and red.

3.4.4. *Chrome Green and Fast Chrome Green*

Chrome greens, C.I.Pigment Green 15:77510 and 77600, are combined or mixed pigments of chrome yellow (see Section Chrome Yellow) and iron blue (see Section Iron Blue Pigments) with the formula

$$Pb(S,Cr)O_4/Fe_4^{III}[Fe^{II}(CN)_6]_3 \cdot xH_2O$$

Fast chrome greens, C.I. Pigment Green 48:77600, 74160, and 74260, are combinations of chrome yellow (see Section Chrome Yellow) and phthalocyanine blue or phthalocyanine green (⟶ Phthalocyanines). For high-grade fast chrome greens, stabilized and highly stabilized chrome yellows are usually used.

The density and refractive index of the chrome greens and fast chrome greens depend on the ratio of the components of the mixture. Their hues vary from light green to dark blue-green, again depending on the ratio of the components.

Production. Chrome green and fast chrome green pigments can be prepared by dry or wet mixing.

Dry Mixing. The yellow and blue or green pigments are mixed and ground in edge runner mills, high-performance mixers, or mills giving intimate contact of the pigment particles. Excessive increase of temperature must be avoided, because this can lead to spontaneous combustion [324]. Differences in the density and particle size of the components can lead to segregation and floating of the pigment components in the coating. Wetting agents are therefore added to avoid these effects [325].

Wet Mixing. Pigments with brilliant colors, high color stability, very good hiding power, and good resistance to floating and flocculation are obtained by precipitating one component onto the other. Solutions of sodium silicate and aluminum sulfate or magnesium sulfate are then added for further stabilization [323].

Alternatively, the components are wet milled or mixed in suspension and then filtered. The pigment slurry is dried, and the pigment is ground.

Uses. Chrome greens have very good dispersibility, resistance to flocculation, bleeding, and floating and very good fastness properties. This is especially true of the fast chrome greens that are based on high-grade phthalocyanine and highly stabilized chrome yellows. They are therefore used in the same applications as chrome yellow and molybdate red pigments (i.e., for the pigmentation of coating media and plastics).

Pigments consisting of zinc potassium chromates combined with blue pigments are no longer of importance.

3.4.5. *Toxicology and Occupational Health*

Occupational Health. Precautions have to be taken and workplace concentration limits have to be observed when handling lead- and lead chromate-containing pigments. General regulations exist for all lead- containing materials [326]. Concentration limits are as follows:

MAK value (lead)	< 0.1 mg/m^3
BAT values	
Lead (blood)	< 70 µg/dL
Lead (blood – women < 45 years)	< 30 µg/dL
δ-Aminolevulinic acid	
(urine, Davies method)	< 15 mg/L
(women < 45 years)	< 6 mg/L
TLV-TWA value (lead)	< 0.15 mg/m^3

It is accepted that the BAT limit has been complied with if the blood lead level does not exceed 50 µg/dL (or for women of < 45 years, 30 µg/dL).

The EEC Directive EEC 82/605 specifies maximum lead concentrations in the air of < 150 µg/m^3 and permitted blood lead levels of 70 – 80 µg/dL, with δ-aminolevulinic acid values of 20 mg/g creatinine [327].

MAK limits for lead chromates and lead chromate pigments are not given. They are classified as substances suspected of having carcinogenic potential (MAK: Group III B; TLV-TWA: 0.05 mg Cr/m^3, A 2). However, extensive epidemiological investigations have given no indication that the practically insoluble lead chromate pigments have any carcinogenic properties [328], [329]. Such properties have been reported for the more soluble zinc chromate and strontium chromate pigments.

These chromate pigments can be safely handled if the various rules and regulations regarding concentration limits, safe working practices, hygiene and industrial medicine are adhered to.

Environmental Aspects. Dust emissions from approved manufacturing plants must not exceed 5 mg/m^3 for lead and chromium with a total mass flow exceeding 25 g/h (TA-Luft) [330].

According to latest German wastewater legislation [332] for inorganic pigment manufacturing processes discharging directly into public stretches of water, mass limits for lead and chromium related to tonnes of average output (t_{prod}) are:

Lead	0.04 kg/t_{prod}
Chromium (total)	0.03 kg/t_{prod}

These requirements replaced earlier legislation dating from 1984 [331]. Lower limits might be set by local or regional authorities, even for “nondirect” discharges into municipal sewer systems.

Waste containing lead and lead chromate that cannot be recycled must be taken to a special waste disposal site under proper control.

Labeling. In the EC lead chromate and lead chromate pigments must be appropriately labeled. Such substances must be marked with a skull and crossbones (T) [333-336]. Additionally, the following risk (R) and safety phrases (S) must be used:

R 61 May cause harm to the unborn child
R 62 Possible risk of impaired fertility
R 33 Danger of cumulative effects
R 40 Possible risk of irreversible effects
S 53 Avoid exposure — obtain special instructions before use
S 45 In case of accident or if you feel unwell, seek medical advice immediately (show the label where possible)

In the 21st adaption of EEC Council Directive 67/548, the lead chromate pigments C.I. Pigment Yellow 34 and C.I. Pigment Red 104 have been added individually [337]. These pigments are classified in the same manner as lead chromate and must be labeled with a skull and crossbones (T) and the above-mentioned risk (R) and safety phrases (S).

According to the EEC Council Directive for the labeling of preparations [338] in conjunction with the 21st adaption to EEC Council Directive 67/548, Nota 1 [337], such materials containing more than 0.5 % lead are labeled in the same way as the pure lead pigment with a skull and crossbones (T) and the corresponding R and S phrases.

With respect to improved protection of public health, special restrictions on carcinogenic and teratogenic substances and their corresponding preparations have been established by the 14th amendment of EEC Council Directive EEC 76/769 [339].

In accordance with the 14th amendment of EEC Council Directive EEC 76/769 [339] and revised ChemVerbV [340], lead chromate based pigments and preparations are no longer permitted to be used by private consumers and have to be labeled with the phrase: “Only for industrial purposes”.

Lead-containing coatings and paints with a total lead content exceeding 0.15 % of the total weight of the preparation must carry the phrase: “Contains lead. Should not be used on surfaces liable to be chewed or sucked by children” in accordance with EEC Council Directive 89/178 [341] and German GefStoffV [333]

Lead chromate pigments are not permitted for use as coloring materials for plastics for consumer goods [342], or for coatings for toys, according to the European Standard EN 71 part 3 [343].

For transportation, the labeling to be used (GGVS/GGVE, ADR/RID) for the pigment as well as for its preparations is Class 6.1, No. 62 c, hazard symbol 6.1 A, and a skull and crossbones, if the lead content soluble in hydrochloric acid [c(HCl) = 0.07 mol/L] exceeds 5 %.

3.5. Ultramarine Pigments

Blue ultramarine — blue from over the sea — is the name which European artists of the Middle Ages gave to the pigment derived from lapis lazuli a semiprecious stone imported mainly from Afghanistan. Ultramarine was the supreme blue of medieval times, but eventually it became scarce and very expensive.

In 1828, J. B. GUIMET in France and CHRISTIAN GMELIN in Germany independently devised similar processes for synthetic preparation. Relatively abundant supplies soon became available, the price fell dramatically, and ultramarine was adopted as a general-purpose color.

Synthetic ultramarines are inorganic powder pigments, commercially available in three colors:

1. Reddish blue, C.I. Pigment Blue 29:77007 [57455-37-5]
2. Violet, C.I. Pigment Violet 15:77007 [12769-96-9]
3. Pink, C.I. Pigment Red 259:77007 [12769-96-9]

A green variety, once produced in small quantities, is no longer available.

Within limits set by stability considerations, the proportions of the chemical constituents can vary. The typical lattice repeat unit of a blue ultramarine is $Na_{6.9}Al_{5.6}Si_{6.4}O_{24}S_{4.2}$. The violet and pink variants differ from the blue mainly in the oxidation state of the sulfur groups. This is reflected in somewhat lower sodium and sulfur contents.

3.5.1. *Chemical Structure*

Reviews of work on the structure of ultramarine are given in [344], [345].

Ultramarine is essentially a three-dimensional aluminosilicate lattice with entrapped sodium ions and ionic sulfur groups (Fig. 32). The lattice has the sodalite structure, with a cubic unit cell dimension of ca. 0.9 nm. In synthetic ultramarine derived from china clay by calcination (see Section Production), the lattice distribution of silicon and aluminum ions is disordered. This contrasts with the ordered array in natural ultramarines.

Figure 32. Schematic drawing of the basic structure of standard ultramarine showing the available sites for sulfur and sodium

In the simplest ultramarine structure, equal numbers of silicon and aluminum ions are present and the basic lattice unit is $Na_6Al_6Si_6O_{24}$ or $(Na^+)_6(Al^{3+})_6(Si^{4+})_6(O^{2-})_{24}$ with a net ionic charge of zero as required for structural stability.

The nature of the sulfur groups responsible for the color is reviewed in [346-348]. There are two types of sulfur group in blue ultramarine, S_3^- and S_2^-, both being free radicals stabilized by lattice entrapment. In the predominant S_3^- species, the spacing between the three sulfurs is 0.2 nm and the angle between them is 103°. S_3^- absorbs a broad

energy band in the visible green – yellow – orange region centered at 600 nm, while S_2^- absorbs in the violet – ultraviolet region at 380 nm (Fig. 33).

Figure 33. Spectral reflectance distribution of blue ultramarine

The basic lattice $(Na^+)_6(Al^{3+})_6(Si^{4+})_6\ (O^{2-})_{24}$ is derived from $Si_{12}O_{24}$ by substituting six of the silicon ions by aluminum. Every Al^{3+} must be accompanied by a Na^+ so that the overall ionic charge for the structure is zero. Hence, six of the eight sodium sites are always filled by sodiums required for lattice stability and the remaining two sites are filled with sodiums associated with ionic sulfur groups. This means that only one S_3^{2-} polysulfide ion can be inserted into the lattice (as Na_2S_3) even though subsequent oxidation to S_3^- (Section Production) leads to loss of one of the accompanying sodium ions. This gives a basic ultramarine lattice formula of $Na_7Al_6Si_6O_{24}S_3$.

To increase the sulfur content and thereby improve color quality, the lattice aluminum content can be decreased by including a high-silicon feldspar in the manufacturing recipe (Section Production). This reduces the number of sodium ions needed for lattice stabilization and leaves more for sulfur group equivalence. A typical product would be $Na_{6.9}Al_{5.6}Si_{6.4}O_{24}S_{4.2}$ with a stronger, redder shade of blue than the simpler type.

In violet (Fig. 34) and pink (Fig. 35) ultramarines, the lattice structure is little changed, but the sulfur chromophores are further oxidized, possibly to S_3Cl^-, S_4, or S_4^-.

Figure 34. Spectral reflectance distribution of violet ultramarine

Figure 35. Spectral reflectance distribution of pink ultramarine

Ultramarines are zeolites, though lattice paths are restricted by 0.4 nm diameter channels. The sodium ions can be exchanged for other metal ions (e.g., silver, potassium, lithium, copper). Although this produces marked color change, none of the products have commercial value.

3.5.2. *Properties*

The basic ultramarine color is a rich, bright reddish blue, the red-green tone varying with chemical composition. The violet and pink derivatives have weaker, less saturated colors (see Figs. 33-35, for reflectance spectra).

The color quality of commercial pigments is developed by grinding to reduce particle size and thus enhance tinting strength. Mean particle size ranges typically from 0.7 to 5.0 µm. Figure 36 shows an electron micrograph of a 1.0 µm grade. Fine pigments are lighter in shade and rather greener than coarser grades, but when reduced with white, their color is brighter and more saturated.

Figure 36. Electron micrograph of blue ultramarine with a mean particle size of 1.0 µm (magnification×5 800)

With a refractive index close to 1.5, similar to that of paint and plastics media, ultramarine gives a transparent blue in gloss paints and clear plastics. Opacity is obtained by adding a small quantity of a white pigment. Increasing quantities of white give paler shades, and a trace of ultramarine added to a white enhances the whiteness and acceptability.

In many applications ultramarine blue is stable to around 400 °C, violet to 250 °C, and pink to 200 °C. All have excellent lightfastness with a 7 – 8 rating (full and reduced shades) on the International Blue Wool Scale. Color fade attributed to light exposure or moderate heat is almost always caused by acid attack. Ultramarines react with all acids, and if there is sufficient acid, the pigment is completely decomposed losing all color to form silica, sodium and aluminum salts, sulfur, and hydrogen sulfide. Evolution of hydrogen sulfide with acids is a useful test for ultramarine. Grades resistant to transient acidity are available, in which the pigment particles are protected by a coating of impervious silica. Blue and violet grades are stable in mildly alkaline conditions, but pink tends to revert to a violet shade.

Ultramarines are insoluble in water and organic solvents, so the color does not bleed or migrate from paints or polymers.

Being macromolecular, the fine ultramarine particles have a high surface energy and are cohesive. The finer grades, with their greater surface area, are therefore less easy to disperse than the coarser types, and some are available with pigment surfaces treated to reduce energy and improve dispersability.

Ultramarines adsorb moisture on the external particle surfaces and at the internal surfaces of the zeolite structure. External surface moisture (1 – 2 % according to particle size) is driven off at 100 – 105 °C, but the additional 1 % of internal moisture needs 235 °C for complete removal.

Ultramarine particles are hard and can cause abrasion in equipment handling either dry or slurried pigment.

Specific gravity is 2.35, but bulk density of the pigment powder is much lower, varying with particle size between 0.5 and 0.9 g/cm^3.

Oil absorption also varies with particle size (usually 30 – 40 g %). The pH lies between 6 and 9. Ultramarine pigments are largely odorless, nonflammable, and do not support combustion.

3.5.3. *Production*

Ultramarine is made from simple, relatively cheap materials, typically china clay, feldspar, anhydrous sodium carbonate, sulfur, and a reducing agent (oil, pitch, coal etc.). Use of a synthetic zeolite has been proposed [349], [350], but this method is not known to be in commercial use.

Clay Activation. The clay is heated to about 700 °C to destabilize the kaolinite structure by removing hydroxyl ions as water. This can be either a batch process with the clay in crucibles in a directly fired kiln, or a continuous process in a tunnel kiln, rotary kiln, or other furnace.

Blending and Heating Raw Materials. The activated clay is blended with the other raw materials and dry-ground, usually in batch or continuous ball mills, to a mean size

approaching 15 µm. Typical recipes (in wt %) are:

	Green-tone	Red-tone
Calcined clay	32.0	30.0
Feldspar		7.0
Sodium carbonate	29.0	27.0
Sulfur	34.5	33.0
Reducing agent	4.5	3.0

The ground mixture is heated to about 750 °C under reducing conditions, normally in a batch process. This can be done in directly fired kilns with the blend in lidded crucibles of controlled porosity, or muffle kilns. The heating medium can be solid fuel, oil, or gas. The sodium carbonate reacts with the sulfur and reducing agent at 300 °C to form sodium polysulfide. At higher temperatures the clay lattice reforms into a three-dimensional framework, which at 700 °C is transformed to the sodalite structure, with entrapped sodium and polysulfide ions.

Oxidation. The furnace is allowed to cool to ca. 500 °C when air is admitted in controlled amounts. The oxygen reacts with excess sulfur to form sulfur dioxide, which exothermically oxidizes the di- and triatomic polysulfide ions to S_2^- and S_3^- free radicals, leaving sodium sulfoxides and sulfur as byproducts. When oxidation is complete, the furnace cools and is unloaded — a full kiln cycle can take several weeks. The “raw” ultramarine product typically contains 75 wt % blue ultramarine, 23 wt % sodium sulfoxides, and 2 wt % free (uncombined) sulfur with some iron sulfide.

Purification and Refinement. The purification and refinement operations can be batch or continuous. The raw blue is crushed and ground, slurried in warm water, then filtered and washed to remove the sulfoxides. Reslurrying and wet grinding release the sulfurous impurities and reduce the ultramarine particle size, often to 0.1 – 10.0 µm. The impurities are floated off by boiling or cold froth flotation.

The liquor is then separated into discrete particle size fractions by gravity or centrifugal separation; residual fine particles are reclaimed by flocculation and filtration. The separated fractions are dried and disintegrated to give pigment grades differentiated by particle size. These are blended to sales-grade standard, adjusting hue, brightness, and strength to achieve specified color tolerance.

Violet ultramarine can be prepared by heating a mid-range blue grade with ammonium chloride at ca. 240 °C in the presence of air. Treating the violet with hydrogen chloride gas at 140 °C gives the pink derivative.

A good ultramarine pigment would meet the following specification:

Tinting strength/standard	± 2 % max.
Reduced shade/standard	1 CIELAB unit max.
Free sulfur	0.05 % max.
Water-soluble matter	1.0 % max.
Sieve residue (45 µm)	0.1 % max.
Moisture	
coarse grade	1.0 % max.
fine grade	2.0 % max.
Heavy metals	traces

For standards see Table 1 (“Ultramarine pigments: specification”).

3.5.4. *Uses*

The stability and safety of ultramarine pigments are the basis of their wide range of applications which include the following:

- Plastics
- Paints and powder coatings
- Printing inks
- Paper and paper coating
- Rubber and thermoplastic elastomers
- Latex products
- Detergents
- Cosmetics and soaps
- Artists' colors
- Toys and educational equipment
- Leather finishes
- Powder markers
- Roofing granules
- Synthetic fibers
- Theatrical paints and blue mattes
- Cattle salt licks
- White enhancement

Plastics. Blue ultramarine can be used in any polymer; violet ultramarine has a maximum processing temperature of 250 °C, and pink ultramarine has a maximum processing temperature of 200 °C. With PVC, acid-resistant grades must be used if color fades during processing. Surface-treated grades are available for enhanced dispersibility. Ultramarines do not cause shrinkage or warping in polyolefins. Ultramarine pigments are permitted worldwide for coloring food- contact plastics.

Paints. Ultramarine pigments are used in decorative paints, stoving finishes, transparent lacquers, industrial paints, and powder coatings. They are not recommended for colored, air-drying paints for outdoor use in urban atmospheres.

Printing Inks. Ultramarine pigments can be used in inks for most printing processes including hot-foil stamping. Letterpress, flexography, and gravure need high-strength grades; lithography needs water-repellent grades; any grade is suitable for screen inks, fabric printing, and hot-foil stamping.

Paper and Paper Coating. Ultramarine pigments are used to enhance the hue of white paper or for colored paper. They can be added directly to the paper pulp, or used in applied coatings. When added to the pulp, acid-resistant grades must be used if acid-sizing is employed. They are particularly suitable for colored paper for children's use.

Detergents. Ultramarine pigments are widely used to enhance the effects of optical brightening agents in improving whiteness of laundered fabrics [351]. They do not stain or build up with repeated use.

Cosmetics and Soaps. Ultramarine pigments are widely used in cosmetics. Pink is not recommended for toilet soaps because of the color shift to violet. Advantages are complete safety, nonstaining, and conformance to all major regulations.

Artists' Colors. This traditional use for ultramarine in all types of media is still an important application. Unique color properties, stability, and safety are highly prized.

Toys and other Articles/Materials for Children's Use. Ultramarine pigments are widely used in plastics and surface coatings for toys, children's paints and finger paints, modeling compositions, colored paper, crayons, etc. They comply with major regulations and standards.

3.5.5. *Toxicity and Environmental Aspects*

Ultramarines are safe in both manufacture and use. Their only known hazard is the evolution of hydrogen sulfide on contact with acid. Massive exposure of workers in well over a century of manufacture, worldwide use for whitening clothes, and use in a number of countries for whitening sugar have all been without reported ill-effects.

Tests sponsored by Reckitt's Colours confirm that acute oral toxicity in rats and mice (LD_{50}) is greater than 10 000 mg/kg. Fish toxicity (LC_{50} in rainbow trout) exceeds

32 000 mg/L. Ultramarine is nonmutagenic, nonirritant, and nonsensitizing to skin.

There is no listed threshold limit value or maximum exposure limit for the pigment. Normal practice is to consider it a nuisance dust with TLV 10 mg/m^3. The pigment is not listed as a dangerous substance in the EC nor in any similar national or international classification; neither is it classified as hazardous for disposal.

The production process evolves close to 1 t of gaseous sulfur dioxide and 0.3 t of water-soluble sodium sulfoxides for every tonne of pigment produced. These must be disposed of in an environmentally acceptable manner. If the soluble salts are fully oxidized, they can be discharged safely into tidal waters. Future legislation in all producing countries may require removal of sulfur dioxide from the effluent gases before discharge to the atmosphere.

3.5.6. *Economic Aspects*

Ultramarines can be categorized as either laundry grades, which are low-strength and sometimes low-purity materials, or as industrial grades, which are high-strength, high-purity pigments.

Factories in several countries produce laundry-grade materials, including several in the People's Republic of China, India, Eastern European countries, and one in Pakistan. Neither the numbers of these units nor their outputs are accurately known.

There are only three major producers of high-grade ultramarine pigments — Dainichi Seika (Japan), Nubiola (Spain), Prayon (Belgium), and Reckitt's Colours (France, United Kingdom) — with two smaller producers in Austria and Colombia. In 1990 total worldwide production was ca. 20 000 t/a.

3.6. Iron Blue Pigments

The term iron blue pigments as defined in ISO 2495 has largely replaced a variety of older names which were either related to the place where the compound was produced or represented particular optical properties (e.g., Berlin Blue, Bronze Blue, Chinese Blue, Milori Blue, Non-bronze Blue, Paris Blue, Prussian Blue, Toning Blue, and Turnbull's Blue). These names usually stood for insoluble pigments based on microcrystalline Fe(II)Fe(III) cyano complexes which do not differ significantly in their composition; many were associated with specific hues. A standardized naming system has been demanded by users and welcomed by manufacturers, and has led to a reduction in the number of names [352].

Iron blue [14038-43-8], C.I. Pigment Blue 27:77510 (soluble blue is C.I. Pigment Blue 27 : 77520), was discovered in 1704 by DIESBACH in Berlin by a precipitation reaction, and can be regarded as the oldest synthetic coordination compound. MILORI was the first to produce it as a pigment on an industrial scale in the early 1800s [353].

3.6.1. *Structure*

X-Ray and infrared spectroscopy show that iron blue pigments have the formula $M^{I}Fe^{II}Fe^{III}(CN)_6 \cdot H_2O$ [354]. M^{I} represents potassium, ammonium, or sodium, of which the potassium and ammonium ions are preferred because they produce excellent hues in industrial manufacture.

The crystal structure of the $Fe^{II}Fe^{III}(CN)_6$ grouping is shown in Figure 37. A face-centered cubic lattice of Fe^{2+} is interlocked with another face- centered cubic lattice of Fe^{3+} to give a cubic lattice with the corners occupied by iron ions. The CN^- ions are located at the edges of the cubes between each Fe^{2+} ion and the neighboring Fe^{3+}; the carbon atom of the cyanide is bonded to the Fe^{2+} ion and the nitrogen atom is coordinatively bonded to the Fe^{3+} ion. According to [355] the deep blue color is the result of electron transfer from iron(II) to iron(III) with the absorption of light energy (charge-transfer complex).

Figure 37. Crystal structure of iron blue [356]

The wide-mesh lattice of the crystal contains relatively large spaces which can be occupied alternately by alkali ions and water molecules. In order to retain the crystal structure — and also the optical properties — water molecules must be present. Loss of water beyond a certain limit brings about fundamental changes in the pigment properties. A bonding mechanism for the coordinated water molecules assumes that both zeolitic and adsorptive states are possible.

Many investigations helped to elucidate the structure of iron blue [357-360].

3.6.2. *Production*

Iron blue pigments are produced by the precipitation of complex iron(II) cyanides by iron(II) salts in aqueous solution. The product is a whitish precipitate of iron(II) hexacyanoferrate(II) $M^{I}_2Fe^{II}[Fe^{II}(CN)_6]$ or $M^{II}Fe^{II}[Fe^{II}(CN)_6]$, (Berlin white), which is aged and then oxidized to the blue pigment [356].

Potassium hexacyanoferrate(II), sodium hexacyanoferrate(II), or mixtures thereof are usually used (⟶ Cyano Compounds, Inorganic). When the pure sodium salt is used, the pigment properties are obtained by adding a potassium or ammonium salt during the precipitation of the white paste product or prior to the oxidation stage.

The iron(II) salt used is crystalline iron(II) sulfate or iron(II) chloride solution. The oxidizing agent can be hydrogen peroxide, alkali metal chlorates, or alkali metal dichromates. Industrial precipitation is carried out batchwise in large stirred tanks by simultaneous or sequential addition of aqueous solutions of potassium hexacyanoferrate(II) and iron(II) sulfate to a dilute acid. The filtrate from the white paste product must contain a slight excess of iron. Temperature and concentration of the starting solutions have a decisive influence on the size and shape of the precipitated particles. The suspension of white paste is aged by heating. The ageing period varies in length and temperature depending on the required properties of the finished pigment. This is followed by oxidation to form the blue pigment by adding hydrochloric acid and sodium or potassium chlorate [361]. Finally, the suspension of the blue pigment is pumped into filter presses either immediately or after having been washed with cold water and decanted. After filtering, it is washed until free of acid and salt.

Depending on the pigment type, the filter press cakes (35 – 60 % solids) are either molded into cylindrical pellets and dried to a finished dust-free product; liquefied and spray dried; or dried and then ground to form a powder pigment.

Dispersibility can be improved by adding organic compounds to the pigment suspension before filtering to prevent the particles from agglomerating too strongly on drying [362], [363]. In another method (the Flushing process), the water in the wet pigment paste is replaced by a hydrophobic binder [364]. Although these and other methods of pigment preparation produce fully dispersible products consisting mainly of iron blue and a binder [365-367], they have not become commercially established.

A “water-soluble” blue can be manufactured by adding peptizing agents, which improve the water solubility by an emulsifying action. This gives a transparent colloidal solution in water without the use of high shear forces [356].

For quality standards, see Table 1 (“Iron blue pigments: Methods of analysis” and “Specification”).

3.6.3. *Properties*

Hue, relative tinting strength, dispersibility, and rheological behavior are the properties of iron blue pigments with the most practical significance. Other important properties are the volatiles content at 60 °C, the water-soluble fraction, and acidity (ISO 2495). Pure blue pigments are usually used alone (e.g., in printing inks) and do not need any additives to improve them. Finely divided iron blue pigments impart a pure black tone to printing ink.

Owing to their small particle size (see Table 26 and Figs. 38 and 39), iron blue pigments are very difficult to disperse. A graph of cumulative particle size distribution is given in Figure 40 for a commercial quality iron blue and for a micronized grade with similar primary particle size. The micronized grade gives greater tinting strength in dry mixtures than the blues obtained from standard grinding. The average size of the aggregates in the micronized material is ca. 10 µm compared with around 35µm for the normal quality product.

Table 26. Physical and chemical properties of iron blue pigments (Vossen Blau and Manox Blue grades)

Type	Vossen Blau 705	Vossen Blau 705 LS [g]	Vossen Blau 724	Manox Blue 460 D	Manox Easisperse HSB 2
Colour Index Number	77 510	77 510	77 510	77 510	77 510

Colour Index Pigment	27	27	27	27	27

LS = Luftstrahlmühle (air jet mill)

Iron blue pigments are thermally stable for short periods at temperatures up to 180 °C, and therefore can be used in stoving finishes. The powdered material presents an explosion hazard; the ignition point is 600 – 625 °C (ASTM D 93–52). The pigments are combustible in powder form; ignition in air is possible above 140 °C [356].

Iron blue pigments have excellent light- and weatherfastness. When mixed with white pigments, these properties can disappear [368]. A clearcoat (as commonly applied in automobile manufacture) overcomes this problem [369]. Figure 41 shows changes in residual gloss and color after a short weathering period. The pigments are resistant to dilute acid and oxidizing agents, and do not bleed. They are decomposed by hot, concentrated acid and alkali. Other properties are listed in Table 26.

Figure 41. Residual gloss and ΔE^*_{ab} values for isocyanate-cross-linked polyacrylate resins that contain 15 wt % Vossen Blau 2000 relative to the binder and 15 wt % TiO_2 (rutile) relative to the iron blue pigment after 1000 h fast exposure to UV [369]

Vossen Blau 2000 is an older pigment type that has been replaced by Manox Blue 460 D

3.6.4. *Uses*

Total production of iron blue in 1975 was ca. 25 000 t/a, but in 1995 it was only ca. 13 000 – 15 000 t/a. The main consumer in Europe and the United States is the printing ink industry. The second largest use in Europe, especially of micronized iron blue pigments, is for coloring fungicides, but use in the paint industry is decreasing.

Printing Ink Industry. Iron blue pigments are very important in printing, especially rotogravure, because of their deep hue, good hiding power, and low cost. Iron blue is often mixed with phthalocyanine pigments for multicolor printing. Another important use is in controlling the shade of black printing inks (⟶ Printing Inks). Typical amounts used are 5 – 8 % for full-shade rotogravure inks and 2 – 8 % for toning black gravure and offset inks.

Iron blue pigments are used in the manufacture of single- and multiple-use carbon papers and blue copying papers, both for toning the carbon black and as blue pigments in their own right [356].

Toning of Black Gravure Inks. For the toning of black gravure inks, 2 – 6 % of Vossen-Blau 705 is used together with 6 – 12 % of carbon black, for example. Combinations with red pigments having a blue undertone are also common. Because of the poor dispersibility of iron blue compared with carbon black it is both economical and practical to disperse the blue pigment in a separate step. While the visual judgement of black is influenced by the individual ability of the observer to distinguish small color differences in deep black, it is possible, with the help of photometric measurements, to graphically interpret objective evaluations by means of physical data [370].

Figure 42 illustrates the color changes of a low-structure LCF carbon black (LCF = low color furnace) on addition of various toners. A mixture of asphalt resin, calcium – zinc resinate and phenolic resin was used as binder. The pigment concentration was 13.2 %, and the toner was added in 2.2 % steps up to 6.6 % with a corresponding reduction of the carbon black content from 13.2 to 6.6 %.

Figure 42. Color coordinates of black gravure inks with various toners

Toning of Black Offset Printing Inks. The basic requirements for the successful use of iron blue as a toning agent in offset printing inks are good dispersibility and resistance to fountain solutions. Resistance is understood here as the hydrophobicity of the pigment. This property prevents wetting of the pigment by water and therefore its peptization. Nonresistant iron blue can render the ink useless by adsorbing water to above the normal content. A negative side-effect of peptization is the “dissolution” of the blue pigment from the printing ink and the resulting blue coloration of the fountain solution, with the familiar problems of printing-plate contamination, also known as scumming or toning. The combined dispersion of pigments is only practical with colorants of similar dispersibility. Toning agents with a considerably higher resistance to dispersion than carbon black are delivered by the manufacturer as a predispersed paste or must be ground separately by the user. A new generation of pigments has been developed which covers the demand for sufficient resistance to fountain solutions combined with good dispersibility. Easily dispersible iron blue is preferred for combined dispersion with carbon black in the so-called co-grinding process. The coloristic effects of these iron blue pigments as toners for an LCF-type carbon black are compared with Pigment Blue 15 : 3 (β-copper phthalocyanine) and Pigment Blue 61 (Alkali Blue) in Figure 43. The pigment concentration of the inks is 24 %; i.e., the amount of carbon black was reduced correspondingly with the addition of 3, 6, or 9 % of blue pigment.

Carbon black used as a self-color pigment has a tendency towards black with a blue untertone at higher pigment concentration, even without the addition of toning agent (1 – 4 in Fig. 43: 15, 18, 21, and 24 % carbon black, resp.). However, without the addition of a blue pigment, the achromatic point cannot be achieved. The desired color hue can be achieved by adding various toning agents, albeit with varying red / green spread. Iron blue (Manox Easisperse 154) brings about a clear shift towards green with a relatively small shift in the blue direction (5 – 7). The target is more successfully achieved by using a mixture of iron blue and Pigment Red 57 : 1 in the ratio 4 : 1 (8 – 10) The addition of Pigment Blue 61 results in a significant step towards blue-red (11 – 13). In addition, a bronze effect occurs and intensifies with increasing distance from the achromatic point. With Pigment Blue 15 : 3, the hue of the black ink moves towards blue-green (14 – 16).

Figure 43. Color coordinates of black offset printing inks with various toners

Agriculture. Since ca. 1935, and especially in Mediterranean countries, blue inorganic fungicides based on copper and used for treating vines have largely been replaced by colorless organic compounds. Micronized iron blue pigments are used to color these fungicides (normally at a concentration of 3 – 8 wt %), so that even small amounts become visible due to the high color intensity, and precise control is possible. The fungicide is usually milled or mixed with a micronized iron blue pigment [371].

A welcome side effect of treating fungi (e.g., *Peronospora plasmopara viticola*) with iron blue is the fertilization of vines in soils that give rise to chlorosis. Leaf color is intensified, aging of the leaves is retarded, and wood quality (“ripeness”) is also improved [372-374]. Iron is necessary for chlorophyll synthesis, which improves grape quality and yield. Other iron salts do not have this effect [373].

Paints and Coatings. Iron blue pigments are used in the paint industry, especially for full, dark blue colors for automotive finishes. A full shade with good hiding power is produced by 4 – 8 % iron blue pigments.

Paper. Blue paper can be produced by adding “water-soluble” iron blue pigment directly to the aqueous phase. Alternatively, a suitable iron blue pigment can be ground together with a water-soluble binder, applied to the paper, dried, and glazed (quantity applied: ca. 10 % in the dispersion).

Pigment Industry. The importance of iron blue in the production of chrome green and zinc green pigments has greatly increased worldwide (see Section Chrome Green and Fast Chrome Green).

Medical Applications. Iron blue has become important as an agent for decontaminating humans and cattle that have ingested radioactive material. The isotope ^{137}Cs which would otherwise be freely absorbed via the human or animal digestive tract exchanges with the iron(II) of the iron blue [375], [376] and is then excreted in the feces [377]. Gelatin capsules containing 500 mg iron blue are marketed as Radiogardase-Cs (Heyl). Thallium ions have been found to behave similarly [378-380]. The gelatin capsules for this purpose are sold as Antidotum Thalii (Heyl) [381].

3.6.5. *Toxicology and Environmental Aspects*

Iron blue pigments show no toxicity in animal studies and are therefore not expected to cause adverse effects on human health. No toxic effects have been reported in humans for blue pigments used experimentally or therapeutically.

Toxikokinetic studies have shown that the adsorption of iron blue pigments is very low. Following intravenous injection of a ^{59}Fe radio-labelled iron blue pigment, the $[^{59}Fe(CN)_6]^{4-}$ion was rapidly and virtually completely excreted with the urine. After oral administration of iron(III) cyanoferrate (^{59}Fe) ca. 2 % of the labelled hexacyanoferrate ion was absorbed by the gastro-intestinal tract [382]. Most of the substance is excreted with the feces [383] and there was no evidence of its decomposition.

The decomposition of iron blue pigment salts to toxic cyanide in aqueous systems is very low. The 5 h CN-release of $KFe[Fe(CN)_6]$ in artificial gastric and intestinal juices was 141 or 26 µg/g respectively, and in water 37 µg/g. The corresponding figures for $Fe_4[Fe(CN)_6]_3$ were 64, 15, and 22 µg/g [384].

In the breath of rats after i.p. injection of ^{14}C-labelled $KFe[Fe(CN)_6]$, less than 0.01 % (detection limit)of the administered radioactivity attributable to ^{14}C-labelled $KFe[Fe(CN)_6]$ was found, whereas in another study 0.04 – 0.08 % of the orally administered dose was found in the exhaled air [385]. It can be concluded that the hexacyanoferrate (II) complex disintegrates only to a small extent in the intestinal tract after oral administration. This is confirmed by the results of acute oral toxicity studies at high doses, which show no clinical symptoms or lethality. The LD_{50} values are above 5000 – 15 000 mg/kg (limit tests) [386-388].

In primary irritation tests on rabbits, no or only slight effects were observed on the skin and in the eyes, respectively [388], [389]. No skin sensitization occurred in a Guinea pig maximization test [386].

The subchronic (90 – 120 d) consumption of iron blue pigments at concentrations of 1 – 2 % in the food or drinking water of rats influenced body weight gain slightly, but no other clinical signs or histopathological changes were observed [390-393]. After the administration of daily doses of 200 or 400 mg/kg for 10 d to dogs, body weight increased and the general condition remained unaffected [394].

In a bacterial test system (Ames test) no increase of mutagenicity was detected with or without the presence of a metabolic system [388].

In human volunteers who received 1.5 or 3.0 g iron(III) hexacyanoferrate(II) for up to 22 d no effects were reported, apart from slight obstipation [394], [395].

Since $Fe_4[Fe(CN)_6]_3$ can bind cesium, iron blue pigments are used in clinical practice as an antidote for the treatment of humans contaminated with radioactive cesium (see also Section Uses). Clinical use of iron(III) hexacyanoferrate(II) in doses up to 20 g/d for decontamination of persons exposed to radioactive cesium has not been associated with any reported toxicity [384].

Iron blue pigment salts are also used as an effective antidote for thallium poisoning. Iron(III) hexacyanoferrate(II) interferes with the enterosystemic circulation of thallium ions and enhances their fecal excretion [397].

In a semistatic acute freshwater fish toxicity test (*Leuciscus idus melanotus*) with a saturated solution of different iron blue pigment compounds (with undissolved material at the bottom or filtered solutions) no death occurred within 96 h. Based on the quantity weighed the NOEL is > 1000 mg/L (nominal concentrations) [398].

The bacterial toxicity has been measured according to DEV, DIN 38 412, L3 [TTC (2,3,5-triphenyl-2*H*-tetrazolium chloride) test]. The result gives an EC_{50} varying between 2290 and 14 700 mg/L, and estimated NOEC values in the range of < 10 to 100 mg/L [399]. There are no harmful effects on fish, but the toxic effects on bacteria constitute a slight hazard when iron blue pigments are present in water.

4. Specialty Pigments

Lutz Leitner, Hendrik Kathrein, Ekkehard Schwab, Helmut Jakusch, Manfred Ohlinger, Ronald Veitch, Günter Etzrodt, Gerhard Pfaff, Klaus-Dieter Franz, Ralf Emmert, Katsuhisa Nitta, Robert Besold, Harald Gaedcke

This chapter deals with pigments that produce special effects: magnetic pigments (Section Magnetic Pigments), anticorrosive pigments (Section Anticorrosive Pigments), luster pigments (Section Luster Pigments), and transparent pigments (Section Transparent Pigments). Luminescent pigments are described elsewhere, see ⟶ Luminescent Materials.

4.1. Magnetic Pigments

For a complete description of magnetic recording media, see ⟶ Information Storage Materials – Magnetic Recording.

4.1.1. *Iron Oxide Pigments*

Ferrimagnetic iron oxide pigments are used in magnetic information storage systems such as audio and video cassettes, floppy disks, hard disks, and computer tapes (⟶ Information Storage Materials). Cobalt-free iron(III) oxide and nonstoichiometric mixed-phase pigments have been used since the early days of magnetic tape technology. Currently, γ-Fe_2O_3 [1309-37-1] and Fe_3O_4 [1317-61-9] (the latter in small amounts) are mainly used in the production of low-bias audio cassettes [iron oxide operating point IEC I standard (International Electrotechnical Commission)], and studio, broadcasting, and computer tapes.

Production. The shape of the pigment particle is extremely important for ensuring good magnetic properties. Isometric iron oxide pigments produced by direct precipitation are seldom used. Since 1947, needle-shaped γ-Fe_2O_3 pigments have been prepared with a length to width ratio of ca. 5:1 to 20:1 and a crystal length of 0.1 – 1 µm [400].

Anisometric forms of Fe_3O_4 with the spinel structure or γ-Fe_2O_3 with a tetragonal superlattice structure do not crystallize directly. They are obtained from iron compounds that form needle-shaped crystals (usually α- and γ-FeOOH, see Section Iron Oxide Pigments) [401-403]. The oxyhydroxides are converted to Fe_3O_4 by dehydration and reduction. Reducing agents may be gases (hydrogen, carbon monoxide) or organic compounds (e.g., fatty acids). The particle geometry is retained during this process.

Since the pigments are subjected to considerable thermal stress during this conversion, the FeOOH particles are stabilized with a protective coating of sintered material (usually silicates [404], phosphates [405], chromates [406], or organic compounds such as fatty acids [407]).

Finely divided stoichiometric Fe_3O_4 pigments are not stable to atmospheric oxidation. They are therefore stabilized by partial oxidation or by complete oxidation to γ-Fe_2O_3 below 500 °C.

In an alternative process, the starting material consists of needle-shaped particles of α-Fe_2O_3 instead of FeOOH pigments [408], [409]. The synthesis is carried out in a hydrothermal reactor, starting from a suspension of $Fe(OH)_3$, and crystal growth is controlled by means of organic modifiers.

Properties. Magnetic pigments with very different morphological and magnetic properties that depend on the field of application and quality of the recording medium, are used. The largest particles (length ca 0.6 µm) are used in computer tapes. The noise level of the magnetic tape decreases with decreasing particle size. Fine pigments are therefore being used increasingly for better quality compact cassettes.

The magnetic properties may be determined by measurement of hysteresis curves on the powder or magnetic tape (⟶ Magnetic Materials – Parameters of Soft Magnetic Materials).

Table 27 shows some quality requirements for the most important applications of magnetic pigments (⟶ Information Storage Materials – Introduction, ⟶ Information Storage Materials – Principles, ⟶ Information Storage Materials – Magnetic Recording Media). Column 4 gives the coercive field strength (H_c) required for information storage materials. The coercive field is the magnetic field required to demagnetize the sample.

Table 27. Some quality requirements for iron oxide and metallic iron magnetic pigments

Field of application	Pigment type	Approximate particle length, µm	Specific surface area, m^2/g	Coercive field strength H_c, kA/m	Saturation magnetization, M_s, $\mu T \cdot m^3/kg$	M_r/M_s
Computer tapes	γ-Fe_2O_3	0.60	13 – 17	23 – 25	86 – 90	0.80 – 0.85
Studio radio tapes	γ-Fe_2O_3	0.40	17 – 20	23 – 27	85 – 92	0.80 – 0.85
IEC I compact cassettes						
standard (iron oxide operating point)	γ-Fe_2O_3	0.35	20 – 25	27 – 30	87 – 92	0.80 – 0.90
high grade	Co – γ-Fe_2O_3	0.30	25 – 37	29 – 32	92 – 98	0.80 – 0.90
IEC II compact cassettes (CrO_2 operating point)	Co – γ-Fe_2O_3, Co – Fe_3O_4	0.30	30 – 40	52 – 57	94 – 98	0.85 – 0.92
IEC IV compact cassettes (metal operating point)	metallic iron	0.35	35 – 40	88 – 95	130 – 160	0.85 – 0.90
Digital audio (R-DAT) *	metallic iron	0.25	50 – 60	115 – 127	130 – 160	0.85 – 0.90
½″ Video	Co – γ-Fe_2O_3 Co – Fe_3O_4	0.30	25 – 40	52 – 57	94 – 98	0.80 – 0.90
Super-VHS video	Co – γ-Fe_2O_3	0.20	45 – 50	64 – 72	94 – 96	0.80 – 0.85
8-mm video	metallic iron	0.25	50 – 60	115 – 127	130 – 160	0.85 – 0.90

* R-DAT: rotary digital audio tape.

The saturation magnetization M_s is a specific constant for the material and for magnetic iron oxides is principally determined by the Fe^{2+} ion content. The ratio of remanent magnetization to saturation magnetization (M_r/M_s) for the tape depends mainly on the orientation of the pigment needles with respect to the longitudinal direction of the tape, and should approach the theoretical maximum value of unity as closely as possible.

Apart from the morphological and magnetic properties, usual pigment properties such as pH value, tap density, soluble salt content, oil absorption, dispersibility, and chemical stability are of great importance for the manufacture of magnetic recording materials.

Producers of magnetic iron oxides include BASF and Bayer (Germany); Ishihara, Sakai, Showa Denko, Titan K., and Toda K (Japan); 3 M, Mitsui, Magnox, ISK Magnetics (USA); Saehan Media (Korea); and Herdilla (India).

World production of cobalt-free magnetic iron oxides in 1995 was ca. 13 000 t, of which ca. 96 % was used in compact cassettes and audio tapes, and ca. 4 % in computer tapes.

4.1.2. *Cobalt-Containing Iron Oxide Pigments*

Cobalt-containing iron oxides form the largest proportion (ca. 75 %) of magnetic pigments produced today. Due to their high coercivity they can be used as an alternative to chromium dioxide for the production of video tapes, high-bias audio tapes (CrO_2 operating point), and high-density floppy disks.

Production. The iron oxide pigments described in Section Iron Oxide Pigments are either doped or coated with cobalt:

1. Body-doped pigments contain 2 – 5 % cobalt that is uniformly distributed throughout the bulk of the pigment particles. It is either incorporated during production of the FeOOH precursor or precipitated as the hydroxide onto one of the intermediate products [410] using cobalt(II) salts as the cobalt source.
2. Cobalt- coated pigment particles (2 – 4 wt % Co) consist of a core of γ-Fe_2O_3 or nonstoichiometric iron oxide phase, and a 1 – 2 nm coating of cobalt ferrite with a high coercivity [411]. The coating can be produced by adsorption of cobalt hydroxide, or epitaxial precipitation of cobalt ferrite in a strongly alkaline medium [412], [413]. Surface- coated pigments show better magnetic stability than doped pigments.

Properties. Pigments with a coercive field strength of 50 – 56 kA/m are used in video cassettes, high-bias audio cassettes (chromium dioxide operating point IEC II), and high-density floppy disks. Depending on the quality of the tape, the particle size varies between 0.2 and 0.4 µm (see Section Iron Oxide Pigments, Table 27).

Pigments with a higher coercive field strength (ca. 70 kA/m) and smaller particle size (particle length ca. 0.15 – 0.2 µm) are used for super VHS cassettes.

Pigments treated with only small amounts of cobalt (0.5 – 1 wt % Co, coercive field strength ca. 31 kA/m) are used as an alternative to cobalt-free γ-Fe_2O_3 pigments for high-quality low-bias audio cassettes. The other parameters described in Section Iron Oxide Pigments are also of importance for cobalt-treated pigments.

Cobalt- containing pigments are mainly produced by the magnetic iron oxide producers listed in Section Iron Oxide Pigments. World production for 1995 was 40 000 t, of which the highest proportion (ca. 85 %) was used for video tapes.

4.1.3. *Chromium Dioxide*

See also ⟶ Chromium Compounds – Chromium(IV) Oxide (Chromium Dioxide), ⟶ Chromium Compounds – Transportation, Storage, and Handling, ⟶ Chromium Compounds – Environmental Protection, ⟶ Chromium Compounds – Ecotoxicology, ⟶ Chromium Compounds – Toxicology and Occupational Health; ⟶ Information Storage Materials.

In the course of the development of pigments for magnetic information storage, CrO_2 was the first pigment material that gave a higher recording density than γ-Fe_2O_3. In the field of audio recording this led to the IEC II standard or “chrome position”.

Physical Properties. Chromium dioxide [12018-01-8], chromium(IV) oxide, CrO_2, is a ferromagnetic material with a specific saturation magnetization M_s/ϱ of 132 A m^2/kg at 0 K corresponding to the spin of two unpaired electrons per Cr^{4+} ion. The M_s/ϱ value of CrO_2 at room temperature is ca. 100 A m^2/kg [414]; CrO_2 magnetic pigments reach values of 77 – 92 A m^2/ kg. The material crystallizes with a tetragonal rutile lattice in the form of small needles which have the desired magnetic shape anisotropy. The morphology of the particles can be varied with several dopants, particularly antimony and tellurium [415]. The coercive field strength (in addition to shape) can be controlled by doping with transition metal ions which modify the magnetocrystalline anisotropy of the material; the Fe^{3+} ion being industrially important [416]. Depending on the iron content up to ca. 3 mol %, H_c values of CrO_2 may vary between 30 and 75 kA/m [417], [418]. Iron doping also increases the Curie temperature from 115 to ca. 170 °C. Because the Fe^{3+} ions are coupled antiferromagnetically with Cr^{4+} ions in the crystal lattice, the saturation magnetization (M_s/ϱ) of CrO_2 decreases with increasing dopant levels [419].

Other important properties of CrO_2 when used as a magnetic pigment are its black color, electrical conductivity (2.5 – 400 Ω^{-1} cm^{-1} [420]) and relatively high crystal hardness (Mohs hardness 8 – 9 [424]). Therefore, coating formulations based on CrO_2 require less or even no additives such as carbon black (good conductivity, black color) or refractory oxides such as alumina.

Chemical Properties. Pure CrO_2 slowly disproportionates in the presence of water. The CrO_2 crystal surface of commercial pigments is therefore topotactically converted to β-CrOOH which serves as a protection layer [421]. The conditions for this reaction have a great influence on the chemical properties of the pigment surface [422], [423]. Thus, the isoelectric point in water can vary between pH 3 and 7 [424], which affects dispersibility. In the absence of moisture, CrO_2 is stable up to ca. 400 °C; above this temperature it decomposes to form Cr_2O_3 and oxygen.

Uses and Economic Aspects. Chromium dioxide is used exclusively for magnetic recording media, e.g., tapes for audio, video, and computer applications. An application of particular interest depends on its relatively low Curie temperature. This allows thermomagnetic duplication at temperatures low enough for the base polymer of magnetic tapes, and is exploited in a commercial, high-speed copying process (⟶ Information Storage Materials – Video Recording) [425]. Chromium dioxide may also be used in combination with cobalt-modified iron oxides (see Section Cobalt-Containing Iron Oxide Pigments) in the production of magnetic recording media. The world production of CrO_2 in 1995 amounted to 8000 t, ca. 11 % of the total consumption of magnetic pigments. Producers are BASF and Du Pont.

4.1.4. *Metallic Iron Pigments*

The magnetization of iron is more than three times higher than that of iron oxides. Metallic iron pigments can have a coercive field strength as high as 150 kA/m, depending on particle size. These properties are highly suitable for high-density recording media (⟶ Information Storage Materials – Metal Particles). Oxidation-resistant products based on metallic pigments first became available in the late 1970s.

Production. Metallic iron pigments are commercially produced by the reduction of acicular (needle-shaped) iron compounds [426]. As in the production of magnetic iron oxide pigments, the starting materials are iron oxide hydroxides (see Section Iron Oxide Pigments) or iron oxalates, which are reduced to iron in a stream of hydrogen either directly or via oxidic intermediates.

Due to their high specific surface area, metallic pigments are pyrophoric, so that passivation is necessary. This can be achieved by slow, controlled oxidation of the particle surface [427].

Properties. The coercive field strength of metallic iron pigments is primarily determined by their particle shape and size, and can be varied between 30 and 150 kA/m. Pigments for analog music cassettes (H_c≈90 kA/m) usually have a particle length of 0.35 µm (see Section Iron Oxide Pigments, Table 27). The length to width ratio of the pigment needles is ca. 10:1. Finely divided pigments (particle length ca. 0.25 µm) with a coercive field strength of 120 kA/m are used for 8-mm video and digital audio cassettes (R-DAT), tapes used by television organizations (ED Beta, Betacam SP MP, M II, Digital Video D 2), and for master video cassettes (mirror master tapes). In the field of data storage, a small quantity is used in micro floppy disks.

Metallic pigments have a higher specific surface area (up to 60 m^2/g) and a higher saturation magnetization than oxidic magnetic pigments. Their capacity for particle alignment corresponds to that of the oxides (see Section Iron Oxide Pigments, Table 27).

Economic Aspects. The largest producers of metallic iron pigments are Dowa Mining, Kanto Denka K., and Mitsui Toatzu.

World consumption in 1995 was ca. 1800 t, of which ca. 75 % was used in the manufacture of video tapes and ca. 14 % for audio tapes, and 11 % for data storage applications. Consumption is expected to increase.

4.1.5. *Barium Ferrite Pigments*

Barium ferrite pigments have been considered for several years for high-density digital storage media [428], [429]. They are very suitable for preparing unoriented (e.g., floppy disks), longitudinally oriented (conventional tapes), and perpendicularly oriented media. In the latter the magnetization is oriented perpendicular to the coating surface. They are required for perpendicular recording systems which promise extremely high data densities, especially on floppy disks (⟶ Information Storage Materials – Perpendicular Recording). Barium and strontium ferrites are also used to prevent forgery of magnetic stripes, e.g., in cheque and identity cards.

Properties. Hexagonal ferrites have a wide range of structures distinguished by different stacking arrangements of three basic elements known as M, S, and Y blocks [430]. For magnetic pigments, the M-type structure (barium hexaferrite [12047-11-9] $BaFe_{12}O_{19}$) is the most important. The magnetic properties of M-ferrite can be controlled over a fairly wide range by partial substitution of the Fe^{3+} ions, usually with combinations of di- and tetravalent ions such as Co and Ti. Barium ferrite crystallizes in the form of small hexagonal platelets. The preferred direction of magnetization is parallel to the *c*-axis and is therefore perpendicular to the surface of the platelet. The specific

saturation magnetization of the undoped material is ca. 72 A m^2/kg and is therefore somewhat lower than that of other magnetic oxide pigments. In barium ferrite the coercive field strength is primarily determined by the magnetocrystalline anisotropy and only to a limited extent by particle morphology. This is the reason why barium ferrite can be obtained with extremely uniform magnetic properties. Barium ferrite pigments have a brown color and chemical properties similar to those of the iron oxides.

Production. There are three important methods for manufacturing barium ferrite on an industrial scale: the ceramic, hydrothermal, and glass crystallization methods. The main producers are Toshiba and Toda.

Ceramic Method. Mixtures of barium carbonate and iron oxide are reacted at 1200 – 1350 °C to produce crystalline agglomerates which are ground to a particle size of ca. 1 µm. This method is only suitable for the high- coercivity pigments required for magnetic strips [431].

Hydrothermal Method. Iron [Fe(III)], barium, and the dopants are precipitated as their hydroxides and reacted with an excess of sodium hydroxide solution (up to 6 mol/L) at 250 –350 °C in an autoclave. This is generally followed by an annealing treatment at 750 – 800 °C to obtain products with the desired magnetic properties. Many variations of the process have been described [432-436], the earliest report being from 1969 [437]. In later processes, hydrothermal synthesis is followed by coating with cubic ferrites, a process resembling the cobalt modification of iron oxides (see Section Cobalt-Containing Iron Oxide Pigments). The object is to increase the saturation magnetization of the material [438-440].

Glass Crystallization Method. This process was developed by Toshiba [441]. The starting materials for barium ferrite production are dissolved in a borate glass melt. The molten material at ca. 1200 °C is quenched by pouring it onto rotating cold copper wheels to produce glass flakes. The flakes are then annealed to crystallize the ferrite in the glass matrix. In the final stage the glass matrix is dissolved in acid. In a variation of this process, the glass matrix is produced by spray drying [442].

Magnetic Recording Properties. Typical values of physical properties of barium ferrite pigments used in magnetic recording are given in Table 28.

Table 28. Typical properties of barium ferrite pigments

Application	Specific surface area, m^2/g	Platelet diameter, nm	Platelet thickness, nm	H_c, kA/m	M_s/ϱ, A m^2/kg
Unoriented (floppy disk)	25 – 40	40 – 70	15 – 30	50 – 65	50 – 65
Oriented	25 – 60	40 – 120	10 – 30	55 – 100	50 – 65
Magnetic strips	12 – 15	100 – 300	50 – 100	220 – 440	60 – 70

Barium ferrite is highly suitable for high-density digital recording mainly because of its very small particle size and its very narrow switching field distribution. It also has a high anhysteretic susceptibility and is difficult to overwrite [443]. This is partly explained by positive interaction fields between particles in the coating layer [444]. The high anhysteretic susceptibility makes barium ferrite media particularly suitable for the anhysteretic (bias field) duplicating process (⟶ Information Storage Materials – Media Requirements for Digital Recording) [445]. Unlike many other magnetic materials used in high-density recording, barium ferrite, being an oxide, is not affected by corrosion [446]. Processing of the pigment can be problematic, e.g., applying orienting fields can easily lead to unwanted stacking of the particles which has adverse effects on the noise level and the coercive field strength of the magnetic tape. A marked temperature dependence of the magnetic properties was a problem in the early days, but this can be overcome by appropriate doping [447].

4.2. Anticorrosive Pigments

4.2.1. *Principles*

Metal corrosion and the relevant electrochemical theory are described elsewhere ⟶ Corrosion. This chapter deals with the protection of metal surfaces against corrosion by means of coatings that contain anticorrosive pigments. The degree of corrosion protection depends not only on the pigment, but also on the binder, and these must complement each other chemically. The uses of anticorrosive pigments in paint binders are summarized in Table 29. For standards, see Table 1 ("Corrosion testing").

Table 29. Possible uses of anticorrosive pigments in various primers

[a] + Commonly used (good anticorrosive properties);
[b] o Anticorrosive properties depend on the formulation;
[c] – Seldom used.
[*] Mainly on aluminum.
[**] Mirror coatings are used to protect the thin metal surface (silver, copper) of metal-coated glass against oxidation or reaction with H_2S or SO_2.

Anticorrosive pigments may be divided into three types [461]:

1. *Pigments with a physical protective action* are chemically inert and are termed *inactive* or *passive*. An example is micaceous iron ore [462], [463]. These lamellar pigments are packed in layers; they lengthen the pathways and obstruct the penetration of ions. They improve adhesion between the substrate and the coating, absorb UV radiation, and protect the underlying binder (Fig. 42), [464-468].
2. *Pigments with chemical protective action* contain soluble components and can maintain a constant pH value in the coating. They are termed *active* and their action depends on reactions in the interfacial areas between the pigment and substrate, pigment and binder, or between pigment and ions that penetrate into the coating [469], [470]. An example is red lead. Redox reactions can occur to form protective compounds (oxides or oxide hydrates that may contain pigment cations). Saponification of the binder or neutralization of the acidic decomposition products enable a definite pH value to be maintained in the coating.
3. *Pigments with an electrochemical protective action* passivate the metallic surface [471], [472]. Those that prevent corrosion of the iron by forming a protective coating (e.g., phosphate pigments) are regarded as being active in the anodic region of the metal surface (anodic protection) [473]. Pigments that prevent rust formation due to their high oxidation potential (e.g., chromates) are said to be active in the cathodic region (cathodic protection) [474].

Figure 44. Schematic representation of the physical anticorrosion effects of flake pigments

Corrosion of iron is explained by the position of iron in the electrochemical series of the elements (Fe/Fe^{2+}: – 0.44 V). In steel, local anode and cathode areas are found due to the presence of phases containing, for example, carbon, carbides, and oxides. These latent local cells are activated by moisture, oxygen, and current- carrying electrolytes and the following reactions occur between the anode areas consisting of iron, and the cathode areas containing carbides or oxides.

Anode:

$$Fe \rightarrow Fe^{2+} + 2e^-$$

$$2Fe^{2+} + O_2 + 2H_2O + 2OH^- \rightarrow 2Fe(OH)_3 \rightarrow 2FeO(OH)[Rust] + 2H_2O$$

Cathode:

$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^-$$

The rust can promote further corrosion. The OH^- ions formed at the cathode produce local high alkalinity and cause hydrolysis of, for example, esterified binders, resulting in detachment of the primer from the substrate [465].

Active anticorrosive pigments inhibit one or both of the two electrochemical partial reactions. The protective action is located at the interface between the substrate and the primer. Water that has diffused into the binder dissolves soluble anticorrosive components (e.g., phosphate, borate, or organic anions) out of the pigments and transports them to the metal surface where they react and stop corrosion. The oxide film already present on the iron is thereby strengthened and sometimes chemically modified. Any damaged areas are repaired with the aid of the active substance. Inhibition by formation of a protective film is the most important mode of action of the commoner anticorrosive pigments.

4.2.2. *Phosphate Pigments*

The most important phosphate- containing pigments are zinc phosphate [448-450], [452]; basic zinc phosphate [451], [452]; chromium phosphate [453]; aluminum triphosphate [454]; barium phosphate [461]; aluminum zinc phosphate [449]; and zinc/iron phosphate [452]. Phosphate ions form protective coatings of basic iron(III) phosphate on an iron surface. Their composition is described in [472]. The phosphating of metal surfaces is described elsewhere, ⟶ Metals, Surface Treatment – Phosphating.

The reactions of phosphate pigments in binders and on metal surfaces were described by G. MEYER [475], and J. RUF [476]. They postulate that basic complexes are formed from phosphate pigments containing water of crystallization and they react with inorganic ions or with carboxyl groups of the binder. Reaction of the pigment with the binder results in physical changes such as deterioration of adhesion or gelling. In paints that contain hydroxy- and carboxy-functional binders, gelling during storage can be prevented by using an excess of alcohol as the solvent.

Toxicological data for phosphate pigments are described in Section Toxicology.

4.2.2.1. *Zinc Phosphate [448-452]*

The most important phosphate- containing pigment is zinc phosphate [7779-90-0], $Zn_3(PO_4)_2 \cdot 4H_2O$, M_r 458.1. It can be used with a large number of binders (see Table 29) and has a very wide range of uses [448], [449], [451], [452], [477].

Zinc phosphate is usually produced on an industrial scale from zinc oxide and phosphoric acid, or from zinc salts and phosphates [478]. Composition and properties are given in Table 30.

Table 30. Composition and properties of zinc and chromium phosphate pigments

Property (standard)	Commercial products		
	Zinc phosphate $Zn_3(PO_4)_2 \cdot 2 – 4 H_2O$	Micronized zinc phosphate $Zn_3(PO_4)_2 \cdot 2 – 4 H_2O$	Chromium phosphate $CrPO_4 \cdot 3 H_2O$
Metal content, wt % (ISO 787, part 2)	51	51	ca. 27
Phosphate content, wt % (ISO 787, part 2)	49	< 49	ca. 47
Chloride content, wt % (ISO 787, part 13)	0.01	0.05	< 0.1
Sulfate content, wt % (ISO 787, part 13)	< 0.1	0.05	0.04
Water-soluble content, wt % (ISO 787, part 3)	< 0.1	0.1	0.4
Sieve residue, wt % (ISO 787, part 18)	0.01	0.01	max. 0.3
Density, g/cm^3 (ISO 787, part 10)	3.2	3.4	2.5

Specific surface area, m^2/g (DIN 66 131/66 132)	1.0	4.3	22
Loss on ignition, wt % (ISO 787, part 2)	10 – 11	13	26
Oil absorption value, g/100 g (ISO 787, part 5)	20	24	65
Conductivity, µS (ISO 787, part 14)	100	300	ca. 500
pH (ISO 787, part 9)	6.2 – 7	7	6.5
Color	white-beige	white-beige	green

The mechanism of the action of zinc phosphate is shown in Figure 43. Zinc phosphate dihydrate pigment is hydrated to the tetrahydrate in an alkyd resin binder [479]. The tetrahydrate is then hydrolyzed to form zinc hydroxide and secondary phosphate ions which form a protective film of basic iron(III) phosphate on the iron surface [475]. The anticorrosive action of zinc phosphate depends on its particle size distribution. Micronization improves the anticorrosive properties [480-482].

Figure 45. Passivation of iron by zinc phosphate [475]

The effect of corrosion-promoting ions on the anticorrosive properties of zinc phosphate is described in [483], [484].

Trade names are as follows:

Zinc phosphate: Sicor ZNP/M, ZNP/S (BASF, Germany); Heucophos ZP 10 (Dr. H. Heubach, Germany); Halox Zinc Phosphate (Halox Pigments, USA); Phosphinox PZ 20 (SNCZ, France); Hispafos N 2 (Colores Hispania, Spain).

Basic zinc phosphate: Heucophos ZPO (Dr. H. Heubach, Germany); Hispafos SP (Colores Hispania, Spain).

4.2.2.2. *Aluminum Phosphate*

Commercial aluminum phosphate anticorrosive pigments consist of aluminum zinc phosphate hydrates [66905-65-5], [449], [451], or zinc- containing aluminum triphosphate [13939-25-8], [454]. Their compositions and properties are listed in Table 31. Their applications in commercial binders are listed in Table 29. Aluminum zinc phosphate hydrate pigments are produced by reacting acid solutions of aluminum hydrogen phosphate with zinc oxide and alkali aluminate. The precipitated pigment is filtered off from the mother liquor, washed, dried, and ground [485]. Commercial aluminum triphosphate pigments contain ions of trimeric phosphoric acid which form stable aluminum-containing iron phosphate complexes [454].

Table 31. Composition and properties of aluminum phosphate anticorrosive pigments

Property	Aluminum triphosphate (commercial product 1; K-White 82) [454]	Aluminum triphosphate (commercial product 2; K-White 84) [454]	Aluminum zinc phosphate hydrate (commercial product 3; Heucophos ZPA, Phosphinal PZ 04) [449], [451]
Al content, wt %	5.5 – 7.7	4.7 – 6.9	4 – 5
Zn content, wt %	11.6 – 14.9	21.3 – 24.5	35 – 39
P_2O_5 content, wt %	42.0 – 46.0	36.0 – 40.0	30/37

pH value	6 – 7	6 – 7	6.5
Water-soluble content, wt %	max. 1.0	max. 1.0	0.1
Color	white	white	white

The aluminum phosphate pigments give good adhesion of the paint film to the metallic substrate.

Trade names are as follows:

Zinc aluminum phosphate: K-White 105 (Teikoku Kako, Japan); Heucophos ZPA (Dr. H. Heubach, Germany); Phosphinal PZ 04 (SNCZ, France).

Aluminum triphosphate: K-White 82, -84 (Teikoku Kako, Japan).

4.2.2.3. *Chromium Phosphate [453], [461]*

Chromium phosphate [16453-74-0], $CrPO_4 \cdot 3\,H_2O$, M_r 201.0, is produced from chromium(III) salts and alkali phosphates. The physical and chemical properties are listed in Table 30; important areas of use are given in Table 29 [453].

Chromium phosphate has a low solubility. It is therefore nearly always used in combination with other anticorrosive pigments. It is an extremely good long-term inhibitor, but is less effective during the initial phase of corrosion protection.

4.2.2.4. *New Pigments Based on Metal Phosphates*

Developments in the field of phosphate pigments are aimed at correcting the deficiencies of phosphate (such as the moderate corrosion protection against accelerated weathering in the salt spray test) during the initial phase of corrosion protection. Improvements include crystallization to form new structures, replacement of cations (e.g., of zinc by calcium), modification of anions (phosphovanadates and phosphocarbonates), optimization of the particle size distribution, providing the zinc ions and phosphate ions in separate compounds, and use of synergistic effects. New pigments are listed in Table 32. Some of them are commercially available, e.g., the zinc molybdatophosphates and zinc calcium molybdatophosphates. Trade names include Heucophos ZMP [449], Moly-White ZNP and MZA [456], and Actirox 102 and 106 [452], [497].

Table 32. New anticorrosive metal phosphate pigments

Composition	Binder	Metal substrate Reference

$CaZn_2(PO_4)_2 \cdot 2\ H_2O$	alkyd resin	iron	[486]
$CaHPO_4 \cdot 2\ H_2O/ZnO$	chlorinated rubber polyvinyl butyral	aluminum	[487]
$CaHPO_4 \cdot 2\ H_2O/ZnO$	phenolic resin alkyd resin	iron	[488]
$MgHPO_4 \cdot 3\ H_2O/ZnO$	polyvinyl butyral	aluminum	[487]
$MgHPO_4 \cdot 3\ H_2O/ZnO$	phenolic resin alkyd resin	iron	[488]
$CaHPO_4 \cdot 2\ H_2O/MgHPO_4 \cdot 3\ H_2O$	alkyd resin	iron	[489]

Mg/Ca phosphovanadate	epoxy, alkyd – melamine	iron	[496]
$[Zn_3(PO_4)_2 \cdot 2 – 4\ H_2O] \cdot [x\ ZnMoO_4]$	alkyd	iron	[449]
$(Zn,Ca)_3(PO_4,MoO_4)_2 \cdot x\ H_2O$	alkyd, epoxy	iron	[456]

4.2.2.5. *Multiphase Phosphate Pigments*

Multiphase anticorrosive phosphate pigments are based on appropriate combinations of inorganic phosphates with sparingly soluble, electrochemically active organic corrosion inhibitors [448]. Examples include Sicor SPO (zinc phosphate with zinc salt of 5-nitroisophthalic acid, BASF) [448]; Sicor NOP (zinc phosphate with calcium salt of 5-nitroisophthalic acid, BASF) [448]; and Heucophos ZPZ (basic zinc phosphate with 0.3 % organic components, Heubach) [449]. The multiphase pigments are produced in one combined synthesis. A slurry of precipitated zinc phosphate is mixed intensively with the zinc or calcium salt of 5-nitroisophthalic acid (Section Organic Pigments), filtered, and washed and ground until the specified conductivity is reached. They are more effective than physical mixtures of pigments produced in separate processes. Multiphase phosphate pigments are used in place of zinc chromate if the anticorrosive effect of pure zinc phosphate is insufficient in the initial weathering phase (e.g., in the salt spray test). The very good anticorrosive effect of multiphase pigments in air-drying alkyd resins or in alkyd – melamine stoving enamels is comparable to that of zinc chromate, even in open air weathering. Commercial multiphase pigments differ mainly in the solubility of the organic corrosion inhibitor. Systems with more soluble inhibitors are used in the binders with a low swelling capacity (e.g., epoxy resins or chlorinated rubber).

The compositions and properties of some commercial multiphase anticorrosive pigments are listed in Table 33. Their anticorrosive properties in various binders are shown in Table 29.

Table 33. Multiphase anticorrosive phosphate pigments (commercial products)

Property	Commercial product 1 (Sicor SPO, BASF) [448]	Commercial product 2 (Sicor NOP, BASF) [448]	Commercial product 3 (Heucophos ZPZ, Heubach) [449]

Phosphate content, wt %	28	30	39
Organic inhibitor content, wt %	2.5	0.5	0.3
Loss on ignition, wt %	9	9	10 – 12
Water-soluble content, wt %	0.9	0.5	0.8
Chloride/sulfate content, wt %	0.02	0.02	<0.05
pH	7	7	7
Conductivity, µS	260	240	650
Density, g/cm^3	3.7	3.8	3.7
Specific surface area, m^2/g	7	5	
Oil absorption value, g/100 g	ca. 20	ca. 20	16
Color	white	white	white
CAS registry no.	[92308-56-0]	[92308-55-9]	[34807-26-6]

Trade names include Sicor SPO, -NOP (BASF, Germany); Heucophos ZPZ (Dr. H. Heubach, Germany); and Novinox PZ 02 (SNCZ, France).

4.2.3. ***Other Phosphorus-Containing Pigments***

Iron Phosphide. Commercial iron phosphide anticorrosive pigments usually consist of Fe_2P [12751-22-3], M_r 142.7, with traces of FeP and SiO_2. The pigment is a powder with a metallic gray color and contains 70 % Fe, 24 % P, 2.5 % Si, and 3.0 % Mn. The density is 6.53 g/cm^3 and the mean particle size is ca. 3 – 5 µm.

Iron phosphide anticorrosive pigments are recommended by manufacturers as replacement materials for zinc dust to reduce the price of zinc-rich paints [498]. For toxicological data, see Section Toxicology.

A *trade name* for iron phosphide is Ferrophos (Hooker Chemicals & Plastics Corp., USA).

Zinc Hydroxyphosphite. Commercial zinc hydroxyphosphite [64539-51-1] is a white, nontoxic pigment with basic character.

The pigment has the following physical properties [457]:

Oil absorption value, g/100 g	15 – 20
Density, g/cm^3	3.96
pH, 2 % suspension	6.5 – 7.5
Mean particle size, µm	2 – 3

Water-soluble content, g/100 cm^3	< 0.01
Specific conductivity, Ω/cm	9700

Its anticorrosive properties in various binders are given in Table 29.

A *trade name* for zinc hydroxyphosphite is Nalcin 2 (National Lead Chemicals, USA; Kronos Titan, Germany).

4.2.4. *Borosilicate Pigments*

Borosilicate pigments [59794-15-19] usually contain calcium or zinc ions in a matrix of silicon dioxide and boron trioxide, x (Ca,Zn) · y SiO_4 · z BO_3. Aqueous slurries of this white pigment are alkaline (pH > 9). Borosilicate pigments are recommended as nontoxic alternatives to basic lead silicate. Their main field of application is in waterborne binders and electrodeposition coatings [450], [499], [500].

A *trade name* for calcium borosilicate is Halox CW 291, -2230 (Halox Pigments, USA).

4.2.5. *Borate Pigments*

Barium metaborate [13701-59-2], BaO · B_2O_3 · H_2O, [459] and zinc borophosphate [84012-98-6], ZnO · x B_2O_3· y P_2O_5 · 2 H_2O, are colorless pigments. Their properties are listed in Table 34; their uses in various binders are listed in Table 29. They both have a relatively high water solubility. Barium metaborate is coated with silica to reduce this.

Table 34. Properties of metal borate pigments

Property	Barium metaborate	Zinc borophosphate
Density, g/cm^3	ca. 3.3	2.8
pH	9 – 10	8
Water-soluble content, wt %	0.4	1 – 1.5
Use	primer, topcoat	primer

The anticorrosive effects of these pigments depend mainly on their ability to maintain high pH values in the coating. They are most effective in the initial phase of corrosion protection. The borate ion neutralizes acidic foreign ions and binder decomposition products, but is also thought to act as an anodic passivator, forming a protective film. The effectiveness of metal borate pigments in aqueous air-dried anticorrosive coatings is described in [501].

The metal borate pigments are classified as having a relatively low toxicity [461], [502]. For toxicological data, see Section Toxicology.

Examples of *trade names* are Butrol (Buckmann Laboratories, USA) for barium metaborate and Sicor BZN (BASF, Germany) for zinc borophosphate.

4.2.6. *Chromate Pigments*

Anticorrosive chromate pigments are summarized in Table 35. Their possible combinations with various binders are listed in Table 29. Standards for specifications of chromate pigments are listed in Table 1.

Table 35. Metallic anticorrosive chromate pigments

Name	Formula	CAS registry no.	Synonym	Appearance	Solubility in water, g/L
Zinc chromate	$ZnCrO_4$	[13530-65-9]	chromic acid – zinc salt (1:1) zinc yellow C.I. Pigment Yellow 36	lemon yellow powder	insoluble
Zinc tetraoxychromate	$ZnCrO_4$ · 4 Zn $(OH)_2$	[15930-94-6]	basic zinc chromate ZTO chromate zinc tetrahydroxychromate C.I. Pigment Yellow 36	yellow powder	ca. 0.04
Basic zinc potassium chromate	4 ZnO · K_2O ·4 CrO_3 · 3 H_2O	[37300-23-5]	basic zinc chromate zinc chromate pigment lemon yellow C.I. Pigment Yellow 36	lemon yellow triclinic flakes	2.5 – 5
Zinc potassium chromate	$KZn_2(CrO_4)_2OH$	[11103-86-9]	chromic acid – potassium zinc salt (2 : 2 : 1) zinc yellow C.I. Pigment Yellow 36	yellow powder	sparingly soluble
Strontium chromate	$SrCrO_4$	[7789-06-2]	strontium chromate A strontium yellow C.I. Pigment Yellow 32	yellow powder	ca. 2

The anticorrosive action of the chromate pigments is based both on chemical and electrochemical reactions [474], [503-508]. Electrochemical passivation and chemical reaction are illustrated in Figure 46 [509], [510]. Passivation is based on electrochemical processes in the cathodic region. In addition, a protective film is also formed by reaction of chromate ions with metal ions at the surface of the substrate to form metal oxide hydrates.

Figure 46. Passivation of iron by chromate pigments [509], [510]

The anticorrosive properties of this class of pigments depend on:

1. The content of water-soluble chromate ions
2. The ratio of water-soluble chromate ions to water-soluble corrosion-promoting ions (chloride and sulfate ions)
3. The active pigment surface in the coating (i.e., particle size distribution and dispersibility)

Chromate- containing pigments are classified as toxic; their use is therefore very limited and they must be appropriately labeled [511], [512]. For a more detailed discussion

of the toxicology of chromates, see Section Toxicology and Occupational Health and ⟶ Chromium Compounds – Toxicology and Occupational Health.

Zinc-Containing Chromate Pigments. Zinc chromate (⟶ Chromium Compounds), is produced by reacting an aqueous slurry of zinc oxide or hydroxide with dissolved chromate ions followed by neutralization, or by precipitation of dissolved zinc salts with dissolved chromate salts. Zinc tetraoxychromate is produced from zinc oxide and chromic acid in an aqueous medium. Basic zinc potassium chromate is obtained by reacting an aqueous slurry of zinc oxide with potassium dichromate and sulfuric acid. The pigments are washed, filtered, dried, and ground.

Trade names include Zinkchromat CZ 20 – CZ 40 (SNCZ, France); Zinkchromat 1W (BASF, Germany); and Zinktetraoxichromat TC 20 – TC 40, LOW DUST (SNCZ, France).

Strontium Chromate. Strontium chromate is precipitated from solutions of sodium dichromate and strontium chloride, followed by filtration, washing, drying, and grinding. A primer composition based on strontium and calcium chromates is described in [513], [451].

A *trade name* for strontium chromate pigments is Strontiumchromat L 203 S – L 203 E (SNCZ, France).

Lead Silicochromate. [514]. Lead silicochromate [11097-70-4], 4 ($PbCrO_4 \cdot PbO$) + 3 ($SiO_2 \cdot 4\ PbO$), is an orange powder. This pigment is a core pigment, in which the active pigment substance ($PbCrO_4$) is precipitated onto an inert core (SiO_2).

In the production process used by National Lead Industries, a solution of chromic acid is added to an aqueous slurry of lead oxide, finely ground silica, and a small amount of basic lead acetate:

$$2\,PbO + CrO_3 \rightarrow PbCrO_4 \cdot PbO$$

The product is heated in a rotary kiln causing the excess lead oxide to react with the basic lead chromate, forming tetrabasic lead chromate:

$$3\,PbO + PbCrO_4 \cdot PbO \rightarrow PbCrO_4 \cdot 4\,PbO$$

On raising the temperature the following reaction takes place on the surface of the silica:

$$4(PbCrO_4 \cdot 4\,PbO) + 3\,SiO_2 \rightarrow 4(PbCrO_4 \cdot PbO) + 3\,(SiO_2 \cdot 4\,PbO)$$

The pigment contains 47.0 wt % PbO, 5.4 wt % CrO_3, and 47.6 wt % SiO_2. Properties are as follows: density 4.2 g/cm^3, oil number 15 g/100 g, tamped volume 163 cm^3 /100 g, sieve residue (> 42 µm) 0.004 wt %, moisture content 0.1 wt %, and pH ca. 7.

A *trade name* for lead silicochromate is Onor (National Lead Chemicals, USA) [457].

4.2.7. *Molybdate Pigments*

Molybdenum-based anticorrosive pigments offer a nontoxic alternative to the zinc chromate pigments [515]. They all have a neutral color (white) but the pure compounds are very expensive. To produce economically competitive pigments molybdate and phosphate pigments are combined, or molybdate compounds are applied to inorganic fillers (e.g., zinc oxide, alkaline-earth carbonates, or talc) [456], [516-518].

Commercially important pigments include basic zinc molybdates ($ZnMoO_4$ [13767-32-3], ZnO [1314-13-2], sodium zinc molybdates ($Na_2Zn(MoO_4)_2$ [11139-48-3]), basic zinc calcium carbonate molybdate, and basic calcium zinc carbonate phosphate molybdate pigments ($CaMoO_4$ [7789-82-4], $CaCO_3$ [471-34-1], ZnO [1314-13-2], $Zn_3(PO_4)_2$ [7779-90-0]). Properties are given in Table 36.

Table 36. Properties of molybdenum-containing pigments

Property	Zinc molybdate pigment	Calcium zinc molybdate pigment	Basic sodium zinc molybdate pigment	Basic calcium zinc phosphomolybdate pigment
Density, g/cm^3	5.06	3.00	4.00	3.00
Oil absorption value, g/100 g	14	18	14	16
Mean particle size, µm (Fisher subsieve sizer)	0.65	1.88	1.02	2.2
pH	6.5	8.5		8

Phosphate- containing molybdate pigments are especially suitable for water-thinnable or latex-based binders, because they improve adhesion to iron substrates. The other molybdate pigments are mainly used in solventborne binder systems.

Unlike chromate ions in chromate pigments, the MoO_4^{2-} ions in molybdate pigments are not chemically reduced in most coatings. Hence, they are ineffective for cathodic protection. Their protective action is assumed to be due to activity in the anodic region, similar to that of phosphate ions. As with the protective phosphate films, molybdate films are very resistant to chloride and sulfate [519]. The duration of maximum activity depends on the metal ions used in the pigment and is probably due to differences in solubility.

Trade names are as follows:

Molybdenum-based: Moly-White 101, 212, 331 (The Sherwin-Williams Company, USA).

Zinc molybdenum phosphate: Actirox 102, -106 (Colores Hispania, Spain); Moly-White ZNP, -MZA (The Sherwin-Williams Company, USA); Heucophos ZMP (Dr. H. Heubach, Germany).

4.2.8. *Lead and Zinc Cyanamides*

Lead cyanamide [20837-86-9], $PbCN_2$, M_r 247.23, is a lemon yellow powder. Zinc cyanamide [20654-08-4], $ZnCN_2$, M_r 105.41, is a white to beige powder. Their properties are listed in Table 37 [520].

Table 37. Properties of lead and zinc cyanamides

Property	Lead cyanamide	Zinc cyanamide
Density, g/cm^3	ca. 6.8	ca. 3.1
Apparent density, g/cm^3	550 – 750	ca. 250
Metal content, wt %	ca. 83	ca. 60
CN_2 content, wt %	ca. 16	ca. 34
Specific surface area, m^2/g	2	ca. 50
pH	9 – 11	8.5
Conductivity, µS	< 300	< 1000

The cyanamides are active anticorrosive pigments which have a passivating action under alkaline conditions. The action of lead in anticorrosive pigments is discussed in Section Red Lead. Heavy metal oxides, especially of iron and manganese, catalyze the conversion of cyanamide to urea even below 20 °C [521]:

$$H_2N-C\equiv N + H_2O \rightarrow H_2N-CO-NH_2$$

At alkaline pH, however, the dimerization of cyanamide to dicyanodiamide is favored. Dicyanodiamide acts as a corrosion inhibitor:

In strongly alkaline solution, hydrolysis to ammonia takes place:

$$H_2N-C\equiv N + H_2O + 2\,OH^- \rightarrow 2\,NH_3 + CO_3^{2-}$$

The main fields of application are in mirror coatings [458], [520], electrodeposition coatings, and primers (see Table 29).

Cyanamide pigments are produced from industrial-grade calcium cyanamide which is first dissolved. Sulfide and phosphide impurities are precipitated as iron or lead salts [522-527] or oxidized [528-530] and filtered off together with graphite impurities. The pure calcium cyanamide is reacted in an aqueous medium with soluble lead or zinc salts or with a slurry of lead oxide or zinc oxide [522], [524], [528], [531-533]. The pigments are filtered, washed, dried, and ground. Zinc cyanamide [534] and pure lead cyanamide are not explosive. An explosion reported during the production of lead cyanamide was caused by contamination with small amounts of acid or nitrates [535].

Zinc cyanamide is nontoxic, but the toxicological classification of lead cyanamide has to take its lead content into account. For toxicological data, see Section Toxicology.

Trade names include Bleicyanamid LY 80, Zinkcyanamid (BASF, Germany).

4.2.9. *Ion-Exchange Pigments*

Ion-exchange pigments were developed as nontoxic alternatives to the chromate pigments. They consist of a silicate carrier (zeolite [536] or amorphous silica gel [537]) to which calcium ions are bound. Commercial ion-exchange pigments have the following properties [538-540]:

pH	ca. 9
Conductivity, µS	ca. 300
Ca content, wt %	ca. 5
Water-soluble fraction, %	ca. 0.9
Oil absorption value, g/100 g	40 – 60
Density, g/cm^3	1.8
Mean particle size, µm	3 – 5
Color	white
Apparent density, g/L	500 – 600

Ion-exchange pigments should be classified as active anticorrosive pigments. They act by exchanging their calcium ions for hydrogen ions in the paint film. In this way acidic chemical substances are neutralized. The calcium ions then bind to the metal oxide surface. The pigments have good anticorrosive properties owing to their high pH value, but the danger of pinholing (depending on the binder) should be pointed out.

A *trade name* for ion-exchange pigments is Shieldex AC3, AC5 (W. R. Grace, UK).

4.2.10. *Metal Oxide Pigments*

4.2.10.1. *Red Lead*

Red lead [1314-41-6], Pb_3O_4, M_r 685.57, crystallizes in the tetragonal system and is a red powder with a density of 9.1 g/cm^3. It decomposes at ca. 500 °C at atmospheric pressure. For standard specifications, see Table 1.

Red lead should be regarded as the lead salt of orthoplumbic acid, H_4PbO_4, i.e., it is lead(II) orthoplumbate, Pb_2PbO_4, in which PbO_6 octahedra are linked by Pb(II) ions [541].

Red lead is produced industrially by oxidizing lead monoxide (PbO) at ca. 460 – 480 °C with agitation in a stream of air for 15 – 24 h. Most red lead is used in the glass, ceramic, and accumulator industries where an apparent density of < 2 g/mL is adequate. For the paint industry, however, highly dispersed red lead is normally necessary, with a sieve residue of < 0.1 % on a 0.063 mm sieve (ISO 787, Part 18) and an apparent density of 1.3 – 2.0 g/mL (ISO 510, DIN 55 516).

The electrochemical action of red lead results from the fact that lead has valencies of 2 and 4 in lead orthoplumbate: Pb(IV) compounds are reduced to Pb(II) in the cathodic region [542]. The chemical anticorrosive effect is a result of lead soaps that are formed when fatty acids in the binder react with the red lead. The lead soaps permeate the paint film as lamellae, and give good mechanical strength, water resistance, and adhesion to the steel surface. Furthermore, the corrosion-promoting chloride and sulfate ions are precipitated by lead(II) ions [543].

Possible combinations of red lead with various binder systems are listed in Table 29 [509]. Red lead is still used for heavy-duty anticorrosion applications, especially for surfaces bearing residual traces of rust. In waterborne paints, red lead has no advantages over zinc phosphate [544].

A *trade name* for red lead is Bleimennige, hochdispers (Heubach & Lindgens, Germany).

4.2.10.2. *Calcium Plumbate*

Calcium plumbate [12013-69-3], Ca_2PbO_4, density 5.7 g/cm^3, is a beige powder formed from lead monoxide and calcium oxide at ca. 750 °C in a stream of air [545].

The anticorrosive properties of calcium plumbate are inferior to those of red lead [509]. Calcium hydroxide is formed as a hydrolysis product when water penetrates through a primer that contains calcium plumbate. The pH at the metal surface then increases to ca. 11 – 12 which inhibits corrosion.

The most important use is in primers for zinc- coated substrates. The pH change occurring on hydrolysis of the calcium plumbate etches the zinc surface which improves adhesion of primers, especially on hot-dip galvanized steel [546].

4.2.10.3. *Zinc and Calcium Ferrites*

Many paint formulations contain iron oxide as an extender. It is a physically protective anticorrosive pigment (only to a small extent). In order to obtain a chemically protective anticorrosive pigment with active constituents the iron oxide is heated with oxides or carbonates of alkaline earths (CaO, $CaCO_3$) or zinc (ZnO) to form pigments of the ferrite type [547], [548]. The following systems have been reported for alkyd resin primers: 2 CaO · Fe_2O_3, CaO · Fe_2O_3 [11119-52-9] and Zn(Mg)O · Fe_2O_3 [68187-51-9]. In the coating these pigments are hydrolyzed with water to form alkaline-earth hydroxides or zinc hydroxide which prevent corrosion by increasing the pH. Alkaline-earth soaps are also formed in certain binder media [549]. However, the pigment volume concentration must be high to ensure good results [550].

Only one zinc ferrite pigment has attained economic significance. Its properties are as follows [551]:

Water-soluble salts, wt %	max. 0.6
Oil absorption value, g/100 g	ca. 22
pH	9 – 11
Density, g/cm^3	5.0

A *trade name* for zinc ferrite is Anticor 70 (Bayer, Germany; Mobay Chemical Corporation, USA).

4.2.10.4. *Zinc Oxide*

Zinc oxide [1314-13-2], ZnO, M_r 81.37, is a white powder that is usually used in combination with active anticorrosive pigments. For a detailed description, see Section Zinc Oxide (Zinc White) . It has the following physical properties:

Oil absorption value, g/100 g	20 – 24
Density, g/cm^3	5.6
Apparent density, cm^3/100 g	100
Mean particle size, µm	0.11 – 0.22
BET surface area, m^2/g	3 – 10

The inhibiting action of zinc oxide is based on its ability to react with corrosive substances and to maintain an alkaline pH in the coating. It also reacts with acidic components of the binder to form soaps and absorbs UV light.

The lead content of commercial zinc oxide depends on the manufacturer and is in the range 0.002 – 1.5 %. For a zinc oxide coating to be considered lead-free, the lead content must be less than 1.5 %.

4.2.11. ***Powdered Metal Pigments***

4.2.11.1. *Zinc Dust*

Zinc dust [7440-66-6], Zn, M_r 65.37, *mp* 419.4 °C, density 7.14 g/cm^3, is a free-flowing blue-gray powder composed of spheroidal particles. It is produced by melting zinc in a crucible, vaporizing it at ca. 900 – 950 °C, and condensing and sifting the product. Alternatively, molten zinc is atomized with a nozzle to produce dust, which is then sifted (⟶ Zinc). Properties of commercial zinc dust pigments are listed in Table 38 [552], [553]. For standard specifications, see Table 1 ("Zinc dust pigments").

Table 38. Properties of commercial zinc dust pigments

Property	Zinc dust Ultra 25	Zinc dust Ultra 35
Total zinc content, wt %	>99.0	>99.0
Metallic zinc content [a], wt %	94 – 96	94 – 96
Lead content, wt %	< 0.005	< 0.005
Cadmium content, wt %	< 0.005	< 0.005
Iron content, wt %	0.003	0.003
Copper content, wt %	0.001	0.001
Acid-insoluble material, wt %	< 0.1	< 0.1
Sieve residue [b], wt %	< 0.01	< 0.01
Mean particle size [c], µm	2.8 – 3.2	3.3 – 3.8

[a] $KMnO_4$ method.
[b] Sieve residue on 16 900 sieve (DIN 4188, aperture: 45 µm).
[c] Air permeability method.

The action of zinc dust in primers with organic binders is based on sealing effects and electrochemical processes. The zinc reacts with water and atmospheric oxygen that diffuse into the binder, forming zinc hydroxide which is then neutralized by sulfuric acid (from SO_2 in the air) and hydrochloric acid (from Cl-containing substances in the air, e.g., NH_4Cl). This causes an increase in volume and decreases permeability. The corrosion products of zinc also have an anticorrosive action [554]. Cathodic protection takes place when the zinc and iron come into contact; the zinc content in the primer must be at least 94 – 96 % [555-558]. Zinc dust coatings are used in large quantities for structural steel, including underwater steel construction and shipbuilding. Zinc dust is also used in inorganic binder systems (alkali silicates or alkyl silicates) in the form of two- component systems [559] (⟶ Paints and Coatings – Alkyl Silicates).

A *trade name* is Zinc Dust Ultra 25 and 35 (Lindgens & Söhne, Germany).

4.2.11.2. *Lead Powder*

Lead powder [7439-92-1], Pb, M_r 207.19, *mp* 327.5 °C, density 11 g/cm^3, is a dark gray powder containing 99 % metallic lead and ca. 0.5 % lead(II) oxide. It is produced by spraying molten lead at ca. 0.5 MPa and sifting. Owing to its high surface area (particle size 1 – 15 µm), it is liable to oxidize, and is therefore supplied in airtight packages or as a paste.

Lead powder can be combined with many binders [560], [561]. It does not affect the stability or viscosity of the paint. Binders that absorb only small amounts of water are particularly suitable (e.g., epoxy resins, chlorinated rubber). When formulating paints based on lead powder, care must be taken not to dilute it with other pigments and extenders by more than 5 vol %.

Lead powder coatings are mainly used for protecting against aggressive chemicals. They have a high UV reflection and extremely good elasticity. Lead powder pigments and pastes are also used in radiological protection.

4.2.12. ***Flake Pigments***

Anticorrosive flake pigments are summarized in Table 39. They increase the barrier resistance of a coating towards water and aggressive gases by increasing the length of the diffusion path in the coating [465-467] (see Section Principles). The interaction between pigment and binder should be as water-resistant as possible to prevent the diffusion of water from the surface of the flakes through the coating.

Table 39. Anticorrosive flake pigments

Pigment	CAS registry no.	Formula	Density, g/cm^3	Color
Micaceous iron ore	[1317-60-8]	Fe_2O_3 (specular hematite)	4.6 – 4.8	dark gray
Talc	[14807-96-6]	$Mg_3Si_4O_{10}(OH)_2$	2.6 – 2.8	white, light green to brown
Muscovite	[114755-46-3]	$KAl_2Si_3AlO_{10}(OH,F)_2$	2.8	gray-white
Phlogopite	[114733-61-8]	$KMg_3AlSi_3O_{10}(OH,F)_2$	2.8 – 2.9	brown
Flake aluminum	[7429-90-5]	Al	2.7	silver
Flake zinc	[7440-66-6]	Zn	7.1	gray

In principle, all lamellar minerals may be used as barrier pigments, e.g., micaceous iron ore [562-564], layer silicates (mica), linear polymeric silicates (wollastonite), and talc [565]. However, untreated mica and talc are not very suitable because they are highly permeable to water [465]. The surface can be modified with, for example, silanes or titanates, to reduce water permeability and improve adhesion [566]. If the chemistry of the treated pigment surface is adapted to the functional groups of the binder, the pigment can be used in aqueous anticorrosive dispersions [567-569].

Flake aluminum pigments with varying platelet thicknesses and shapes are used for corrosion protection [570]. For standard specifications, see Table 1 ("Aluminum pastes and pigments"). They are coated with a water-repellent, fatty film and are therefore particularly suitable for conventional solventborne coating systems. They have outstandingly good weather resistance [570-572].

Flake zinc pigments have a barrier effect and also act by a cathodic anticorrosive mechanism. Compared with zinc dust coatings, flake zinc pigments are formulated with lower pigment volume concentrations [573].

4.2.13. *Organic Pigments*

Unlike soluble inhibitors, organic anticorrosive pigments are sparingly soluble organic compounds or metallic salts of organic acids and are used in binders instead of, or in addition to, inorganic anticorrosive pigments. Inhibitors are not viable substitutes for active anticorrosive pigments in coatings [574]. Organic anticorrossive pigments were developed to replace toxic, chromate-based anticorrosive pigments.

Trade names include Sicorin RZ (BASF, Germany); Alkophor 827 (Henkel, Germany); and Irgakor 252 (Ciba-Geigy, Switzerland).

The zinc salt of 5-nitroisophthalic acid [60580-61-2] [448] is produced as an easily dispersible pigment by a wet chemical process from 5-nitroisophthalic acid and zinc oxide [575]. It has the following properties:

Color	colorless
Density, g/cm^3	2.5
Oil absorption value, g/100 g	40
Bulkiness, cm^3/100 g	650
Specific surface area, m^2/g	16
Heat resistance, °C	ca. 300
Zinc content, wt %	ca. 44
Organic content, wt %	ca. 49
Chloride content, wt %	ca. 0.02
Sulfate content, wt %	ca. 0.03
Nitrate content, wt %	ca. 0.01
Volatile content, wt %	ca. 5
Water-soluble content, %	ca. 1.6
pH	7.2
Conductivity, µS	ca. 500

A less expensive replacement for zinc chromate is obtained by combining the zinc salt of 5-nitroisophthalic acid with zinc phosphate pigments (Section Multiphase Phosphate Pigments) [448], [473], [576]. A concentration of 0.5 – 2.0 % based on the liquid coating is recommended.

The electrochemical anticorrosive action of the zinc salt of 5-nitroisophthalic acid is comparable with that of zinc potassium chromate [577].

Table 29 gives possible combinations with binders. The compound is nontoxic (see Section Toxicology).

Other Organic Anticorrosive Pigments. The following organic anticorrosive pigments are either commercial products or have been reported in the literature:

1. (2-Benzothiazolylthio)succinic acid [578], [579]
2. Zinc mercaptobenzothiazole [580], [581]
3. Basic zinc salt of *N*-benzosulfonylanthranilic acid [448], [582]

They are used in the binder at concentrations of 0.5 – 2.0 %, if possible in combination with zinc phosphate or other suitable anticorrosive pigments. For toxicological data, see Section Toxicology.

4.2.14. *Toxicology*

The change in the toxicological classification of lead- and chromate-based anticorrosive pigments has resulted in reappraisal of the formulation of anticorrosive coatings.

Acute oral toxicities (LD_{50}) of anticorrosive pigments are given in Table 40. For a detailed description of the toxicology of lead, see ⟶ Lead – Toxicology and Occupational Health; for chromates, see ⟶ Chromium Compounds – Toxicology and Occupational Health.

Table 40. Acute oral toxicity of anticorrosive pigments

Pigment	LD_{50} (rat), mg/kg	Reference
Zinc phosphate	> 5000	[448]
Aluminum triphosphate	> 11 000	[454]
Multiphase phosphate pigment	> 5000	[448]
Iron phosphide	> 21 500	[494]
Barium metaborate	850	[459]
Zinc potassium chromate *	> 640	[448]
Zinc tetraoxychromate *	> 5000	[448]
Calcium, zinc carbonate/molybdate	> 5000	[456]
Zinc molybdate	11 800	[456]
Lead cyanamide	3 500	[448]
Zinc cyanamide	< 1 800	[448]
Red lead	> 15 000	[583]
Zinc oxide	> 10 000	[584]
Zinc salt of 5-nitroisophthalic acid	> 10 000	[448]
Basic zinc salt of *N*-benzosulfonylanthranilic acid	> 4 000	[448]
Zinc mercaptobenzothiazole	> 5 000	[580]
2-Benzothiazolylthiosuccinic acid	> 5 000	[579]

* Classified as a carcinogenic substance in Section III A1 of the list of MAK values.

4.3. Luster Pigments

As shown in Figure 47 A, *conventional pigments* interact with light by absorption and/or diffuse scattering (see Section Color Properties). Luster pigments comprise nacreous pigments (Section Nacreous and Interference Pigments) and metal effect pigments (Section Metal Effect Pigments).

Figure 47. Optical principles of conventional and luster pigments

A) Conventional pigment that absorbs and scatters light; B) Metal effect pigment with complete regular reflection; C) Natural pearl composed of alternating layers of protein and $CaCO_3$; D) Nacreous pigment: the pearl is simulated by parallel orientation of the pigment platelets

Nacreous pigments simulate the nacreous luster of natural pearls (Fig. 47 C), which consist of alternating, transparent layers of materials with a high ($CaCO_3$) and a low (protein) refractive index. Small platelets of a high-refractive-index material (i.e., the nacreous pigment) are oriented in parallel alignment in a matrix of lower refractive index, e.g., a paint binder or plastic (Fig. 47 D). Synthetic nacreous pigments are transparent or light-absorbing platelet crystals. They may also have a multilayer structure, the layers having different refractive indices and light absorption properties.

Metal effect pigments (Fig. 47 B) consist of small metallic flakes (mainly aluminum or Cu/Zn bronze) which act as small mirrors that reflect almost all of the incident light.

4.3.1. *Nacreous and Interference Pigments*

Synthetic or natural pigments used to achieve lustrous, brilliant, or iridescent color effects by interference on thin optical films are called nacreous or pearlescent pigments [585-589]. They were originally used to simulate the appearance of natural pearls. The visual effects produced by reflection and transmittance of light by thin multilayer films are not restricted to pearls and shells but are widespread in nature [590]. Extending GREENSTEIN's definition [586], nacreous (pearlescent) pigments are "thin platelets of high refractive index which partially reflect and partially transmit light," or contain layers of this kind. DIN 55 943 (April 1990) proposes the comprehensive term "interference pigments" for nacreous pigments consisting of materials that do not absorb visible light (e.g., TiO_2) or that contain materials with a high refractive index and additional absorption characteristics (e.g., Fe_2O_3). However, in this article the term "nacreous pigments" is used.

The use of pearls and nacreous shells for decorative purposes goes back to ancient times (e.g., in Chinese wood intarsia). The history of pearl pigments dates back to 1656, when the French rosary maker JAQUIN isolated a silky lustrous suspension from fish scales (pearl essence) and applied this to small beads to create artificial pearls [591]. It took more than 250 years to isolate the pearl essence material (guanine platelets) and understand the pearl effect [592]. Attempts were made to create synthetic pearl colors as organic or inorganic, transparent, highly refractive coatings and pearl pigments as crystalline platelets [593]. From 1920 onwards hydroxides, halides, phosphates, carbonates, and arsenates of zinc, calcium, barium, mercury, bismuth, lead, and other cations were produced for this purpose. Only the traditional natural pearl essence (Section Natural Pearl Essence), basic lead carbonate (Section Basic Lead Carbonate), and bismuth oxychloride (Section Bismuth Oxychloride) are still of importance.

The strong demand for pearl effects came from the growing coatings and plastics industries who wanted to improve the acceptance and popularity of their products. Furthermore, nacreous pigments also allowed artists and designers to create new visual effects similar to those found in nature [594], [595]. The breakthrough for nacreous pigments came with the invention of mica coated with metal oxides (Section Metal Oxide – Mica Pigments) [596]. Mica-based nacreous pigments now account for > 85 % of the world market.

Important nacreous pigments and producers are listed below:

- Natural pearl
  - Engelhard Corp./Mearl, NJ, USA
- Basic lead carbonate
  - J. Jaeger GmbH, Viechtach, Germany
  - Polipearl S.A., Argentina
  - Semo Ltd., Seoul, South Korea
- Bismuth oxychloride
  - Engelhard Corp./Mearl , NJ, USA
  - Rona, N.J., USA (subsidiary of Merck KGaA)
- Metal oxide – mica
  - BASF, Ludwigshafen, Germany
  - Kemira OY, Pori, Finland
  - Engelhard Corp./Mearl , NJ, USA
  - Merck KGaA, Darmstadt, Germany (and overseas subsidiaries: E.M. Industries, NY, USA; Merck Japan Ltd., Onahama, Japan)

Nacreous pigments are used to obtain pearl, iridescent (rainbow), or metallic effects, and in transparent color formulations to obtain brilliance or two-tone color and luster flops (change with viewing angle). The most important applications are plastics, coatings, printing inks, cosmetics, and automotive paints. The two major nacreous pigment producers, Merck KGaA and Engelhard Corp./Mearl, do not publish production data.

Table 41 shows an overview of pigments with luster effects. Effect pigments can be classified as metal platelets, oxide-coated metal platelets, oxide-coated mica platelets, platelet-like monocrystals, and comminuted PVD films (PVD = physical vapor deposition). Aims of new developments are new effects and colors, improvement of hiding power, more intense interference colors, increased of light and weather stability, and improved dispersibility. Of special interest are pigments which are toxicologically safe and which can be produced by ecologically acceptable processes.

Table 41. Overview of effect pigments [597]

Pigment type	Examples
Metallic platelets	Al, Zn/Cu, Cu, Ni, Au, Ag, Fe (steel), C (graphite)
Oxide-coated metallic platelets	surface-oxidized Cu and Zn/Cu platelets, Fe_2O_3-coated Al platelets
Coated mica platelets	
nonabsorbing coating	TiO_2 (rutile), TiO_2 (anatase), ZrO_2, SnO_2, SiO_2
selectively absorbing coating	FeOOH, Fe_2O_3, Cr_2O_3, TiO_{2-x}, TiO_xN_y,$CrPO_4$, $KFe[Fe(CN)_6]$
totally absorbing coating	Fe_3O_4, TiO, TiN, $FeTiO_3$, C, Ag, Au, Fe, Mo, Cr, W
Platelet-like monocrystals	BiOCl, $Pb(OH)_2 \cdot 2\ PbCO_3$, α-$Fe_2O_3 \cdot n\ SiO_2$, $Al_xFe_{2-x}O_3$, $Mn_yFe_{2-y}O_3$, $Al_xMn_yFe_{2-x-y}O_3$, Fe_3O_4, reduced mixed phases, Cu phthalocyanine
Comminuted PVD films	Al, Al (semitransparent)/SiO_2/Al/SiO_2/Al (semitransparent)

4.3.1.1. *Optical Principles*

Nacreous and Interference Pigments. The optical principles of nacreous (interference) pigments are shown in Figure 48 for a simplified case of nearly normal incidence without multiple reflection and absorption. At the interface P_1 between two materials with refractive indices n_1 and n_2, part of the beam of light L_1 is reflected (L_1') and part is transmitted (i.e., refracted) (L_2). The intensity ratios depend on n_1 and n_2 (⟶ Optical Materials – Optical Properties of Optical Materials). In a multilayer arrangement as found in pearl or pearlescent and iridescent materials (Fig. 47 C) [587], each interface produces partial reflection. After penetration through several layers, depending on the size and difference between n_1 and n_2, virtually complete reflection is obtained, provided that the materials are sufficiently transparent [595].

Figure 48. Simplified diagram showing nearly normal incidence of a beam of light (L_1) from an optical medium with refractive index n_1 through a thin solid film of thickness d with refractive index n_2

L'_1 and L'_2 are regular reflections from phase boundaries P_1 and P_2. L_3 represents diffuse scattered reflection from the transmitted light.

In pigments that simulate natural pearl effects, the simplest case is a platelet-shaped particle with two phase boundaries P_1 and P_2 at the upper and lower surfaces of the particles, i.e., a single, thin, transparent layer of a material with a higher refractive index than its surroundings. For small flakes with a thickness of ca. 100 nm, the physical laws of thin, solid, optical films apply [598].

Multiple reflection of light on a thin solid film with a high refractive index (Fig. 48) causes interference effects in the reflected light and in the complementary transmitted light. For the simple case of nearly perpendicular incidence, the intensity of the reflectance (I) depends on the refractive indices (n_1, n_2), the layer thickness (d), and the wavelength (λ) [599], [600]:

$$I = \frac{A^2 + B^2 + 2AB\cos\theta}{1 + A^2B^2 + 2AB\cos\theta}$$

$$A = \frac{n_1 - n_2}{n_2 + n_1} \quad B = \frac{n_2 - n_1}{n_2 + n_1} \quad \theta = 4\pi\frac{n_2 d}{\lambda}$$

With given n_1 and n_2 the maximum and minimum intensities of the reflected light — seen as interference colors — can be calculated and agree well with experimental results [601]. Refractive indices of materials commonly used in nacreous pigments follow:

Vacuum/air	1.0	$Pb(OH)_2 \cdot 2\,PbCO_3$	2.0
Water	1.33	BiOCl	2.15
Proteins	1.4	Carbon (diamond)	2.4
Plastics	1.4 – 1.7	Fe_3O_4	2.4
Mica	1.5	TiO_2 (anatase)	2.5
$CaCO_3$ (aragonite)	1.68	TiO_2 (rutile)	2.7
Natural pearl (guanine, hypoxanthine)	1.85	Fe_2O_3 (hematite)	2.9

In practice platelet crystals are synthesized with a layer thickness *d* calculated to produce the desired interference colors (iridescence) [601], [602]. Most nacreous pigments now consist of at least three layers of two materials with different refractive indices (Fig. 49). Thin flakes (thickness ca. 500 nm) of a material with a low refractive index (mica) are coated with a highly refractive metal oxide (e.g., TiO_2, layer thickness ca. 50 – 150 nm). This results in particles with four interfaces that constitute a more complicated, but still predictable thin film system. The behavior of more complex multilayer pigments containing additional, thin, light-absorbing films can also be calculated if appropriate optical parameters are known [601].

Figure 49. Simplified scheme of light reflection at the phase boundaries of a metal oxide – mica pigment

Color effects depend on the viewing angle [602-606]. Nacreous pigment platelets split white light into two complementary colors that depend on the platelet thickness. The reflected (interference) color dominates under regular (maximum) reflection, i.e., when the object is observed at the angle of regular reflection (Fig. 50 B). The transmitted part dominates at other viewing angles under diffuse viewing conditions provided there is a nonabsorbing (white) or reflecting background (Fig. 50 A). Variation of the viewing angle therefore produces a sharp gloss (reflectance) peak, and the color changes between two extreme complementary colors [602], [605]. The resulting complex interplay of luster and color is measured goniophotometrically in reflection and at different angles (⟶ Dyes, General Survey) [601]. No general standard measurement geometries have yet been specified. However, colorimetric analysis always includes measurements close to regular conditions and under diffuse conditions. This can be done, for example, by tilting a standard pigmented film on a drawdown card (Fig. 50). The colorimetric data are interpreted according to CIE $L^*a^*b^*$ data. A nacreous pigment is characterized by a minimum of three $L^*a^*b^*$ data sets measured under different conditions (e.g., 0°/45° black background, 22.5°/22.5° black background, 0°/45° white background). An analysis of these data specifies a pigment on the basis of its hiding power, luster, and hue [604]. The influence of other measurement geometries, especially of different commercially available instruments, is discussed in [601], [602].

Figure 50. Colorimetric determination of nacreous pigments

The platelet particles are incorporated in a lacquer of defined thickness on a standard black and white drawdown card. The card is mounted on a rotatable sample holder and measured under (A) 0°/45° (diffuse reflection) and (B) 22.5°/22.5° (regular reflection, luster).

Against a black background or in a blend with carbon black, the transmitted light is absorbed and the reflected interference color is seen as the mass tone (i.e., overall color) of the material. In blends of nacreous pigments with absorbing colorants, the particle size of the latter must be well below the scattering limit, i.e., they must be transparent (see Section Transparent Pigments). The nacreous effect or iridescent reflection is otherwise quenched by the hiding pigments. This also applies to blends with strongly reflecting metal effect pigments (e.g., aluminum). Blends of pigments with different interference colors obey an additive mixing law, (e.g., blue + yellow = white) instead of the subtractive color mixing of pure absorption pigments (e.g., blue + yellow = green) [602].

The behavior of combinations of interference pigments with absorption and/or metal effect pigments is too complicated to predict and requires thorough goniophotometric analysis. The nacreous pigment effects generally dominate under regular (gloss) viewing conditions, and the absorbing colorant under diffuse viewing conditions [606].

4.3.1.2. *Natural Pearl Essence [589], [591], [606-611]*

Natural pearl essence (Essence d'Oriente, Fish Silver) — a pigment suspension derived from fish scales, skin, or bladder — is the oldest commercial pearl luster pigment. It consists mainly of a mixture of the purines guanine [73-40-5] (75 – 97 %) and hypoxanthine [68-94-0] (25 – 3 %). The ratio of these two purines depends on the fish species (mainly herrings, sardines, and other white fish) and their geographical origin (Japan, Norway, and the northeast U.S. – Canadian coastal border).

The pigments are formed in the fish scales as platelet-shaped crystals (0.05 µm × 1 – 10 µm × 20 – 50 µm). A commercial synthetic process for producing purines with this crystal shape has not been found. An aqueous suspension of fish scales is therefore extracted with organic solvents to dissolve and remove the proteins. The remaining dispersion contains purine crystals and scale, which are separated from one other by a complicated washing and phase-transfer process [611].

Due to its tendency to agglomerate in dry form, natural pearl essence is handled as a 22 – 25 % dispersion in various media (e.g., nitrocellulose lacquer for nail enamel, aqueous or alcoholic media for lotions or shampoos) It is used almost exclusively in cosmetic applications [611]. Despite the high price, natural pearl essence has several advantages over synthetic pearlescent pigments: it is less fragile; has a low density (1.6 g/cm^3), which reduces settling in liquid formulations; and has a very high, but soft luster (n = 1.79 – 1.91, the highest value being along the shortest axis). The world market for natural pearl essence in 1995 was estimated to be less than 50 t.

4.3.1.3. *Basic Lead Carbonate [585-589], [612], [613]*

The first commercially successful synthetic nacreous pigments were hexagonal platelet crystals of lead salts: thiosulfate, hydrogenphosphate, hydrogenarsenate, and most important nowadays, basic carbonate. Basic lead carbonate [1319-46-6] $Pb(OH_2) \cdot 2\,PbCO_3$, M_r 775.7, is precipitated from aqueous lead acetate or lead propionate solutions with carbon dioxide.

$$3\,Pb(OCOCH_3)_2 + 2\,CO_2 + 4\,H_2O \rightarrow 2\,Pb(OH)_2 \cdot 2\,PbCO_3 + 6\,CH_3COOH$$

Under appropriate reaction conditions regular hexagonal platelets (ca. 50 nm thick and 20 µm in diameter) can be obtained. The high refractive index (n = 2.0), high aspect ratio (> 200), and the extremely even surface of basic lead carbonate make it an optical match to natural pearl essence.

The platelet thickness can be adjusted to produce interference colors by modifying the reaction conditions. When aligned with its plane orthogonal to the incident light, the platelet crystal behaves as a thin, solid, optical film (see Fig. 48) with two phase-shifted reflections from the upper and lower crystal planes (the phase boundaries).

The crystals are mechanically sensitive, and their high density (6.4 g/cm^3) results in fast sedimentation. In view of their agglomeration tendency and occupational health (toxicity) risks they are not produced in powder form, but are flushed from the aqueous phase into suitable organic solvents or resins and handled as stabilized dispersions.

Currently, use of basic lead carbonate is limited to artificial pearls, buttons, and bijouterie. Due to the low chemical stability of this pigment and toxicity problems, it is being increasingly replaced by bismuth oxychloride and mica-based pigments. Worldwide production of basic lead carbonate pigment in 1995 was ca. 1000 t.

4.3.1.4. *Bismuth Oxychloride [585-589], [614]*

Powders containing bismuth compounds have long been used for decorative purposes to generate a shiny luster or lustrous colors (e.g., facial cosmetic powders in ancient

Egypt, imitation pearls made by coating glass and ceramic beads). Bismuth oxychloride [7787-59-9], bismuth oxide chloride, BiOCl, M_r 260.4, was the first synthetic nontoxic nacreous pigment. It is produced by hydrolysis of acidic bismuth solutions in the presence of chloride ions. Precipitation conditions may be varied (concentration, temperature, pH, pressure) or surfactants added to obtain the desired crystal quality. The virtually tetragonal bipyramidal structure is thereby “squashed” into a flat platelet.

Pure BiOCl is available in three grades with different nacreous effects that depend on the aspect ratios and crystal size:

1. Low- or medium-luster powder (aspect ratio 1 : 10 to 1 : 15), mainly used as a highly compressible, white, lustrous filler with excellent skin feel
2. Dispersion of high luster quality (aspect ratio 1 : 20 to 1 : 40) consisting of square or octagonal platelets in nitrocellulose lacquers (nail polish) or castor oil (lipsticks)
3. Dispersion of very high luster quality (aspect ratio > 1 : 50) consisting of lens-shaped platelets in nitrocellulose lacquer, castor oil, or butyl acetate

Pigments consisting of BiOCl- coated mica or talc and blends of BiOCl with other organic or inorganic colorants are also available.

The dominant market for BiOCl is still the cosmetic industry. Its low light stability (it turns from silver white to metallic gray in sunlight), relatively high price, fast settling (high density, 7.73 g/cm^3), and mechanical sensitivity limit its use in technical applications. Although the darkening reaction is not yet understood, low-luster grades with improved light stability are available. Some manufacturers promote the combination with UV stabilizers for technical purposes. Uses are in the button industry, bijouterie, printing, and for X-ray contrast in catheters. The world market is ca. 500 t/a.

4.3.1.5. *Metal Oxide – Mica Pigments*

The dominant class of nacreous pigments is based on platelets of natural mica coated with thin films of transparent metal oxides (see Fig. 49). Mica minerals are sheet layer silicates and are described in detail elsewhere (⟶ Mica). Nacreous pigments are usually based on transparent muscovite [99401-63-5] but some are based on natural or synthetic phlogopite [110710-26-4]. Although muscovite occurs worldwide, few deposits are suitable for pigments; it is biologically inert and approved for use as a filler and colorant [615], [616].

Selection and pre-processing of the mica substrate is one of the key factors which determine the quality and appearance of nacreous pigments. The aspect ratio of the final pigment depends on the particle size distribution of the mica platelets, which have a thickness of 300 – 600 nm and various diameter ranges (e.g., 5 – 25, 10 – 50, 30 – 110 µm). Since light is regularly reflected from the planes of the metal-oxide- coated mica and scattered from the edges, brilliance and hiding power are inversely related to each other.

A mica pigment coated with a metal oxide has three layers with different refractive indices and four phase boundaries $P_1 – P_4$: (P_1) TiO_2 (P_2) mica (P_3) TiO_2 (P_4). Interference of light is generated by reflections of all six combinations of phase boundaries, some of which are equal: $P_1P_2 = P_3P_4$, $P_1P_3 = P_2P_4$, P_1P_4, and P_2P_3. The thickness of the mica platelets varies in accordance with a statistical distribution. Consequently, interference effects involving the phase boundaries between the mica substrate and the oxide coating add together to give a white background reflectance. The interference color of a large number of particles therefore depends only on the thickness of the upper and lower metal oxide coating layers [586], [599], [600].

The development of the mica-based pigments started with pearlescent colors (Fig. 51 A, TiO_2 – mica). It was followed by brilliant, mass-tone- colored combination pigments (i.e., mica, TiO_2, and another metal oxide) with one color (interference color same as mass tone) or two colors (interference and mass tone different) that depend on composition and viewing angle (Fig. 51 B). In the 1980s further development was made by coating mica particles with transparent layers of iron(III) oxide (Fig. 51 C) [617].

Figure 51. Upper half of metal oxide – mica pigments

Increasing layer thickness of metal oxide causes different interference colors in reflection. Combination with absorption colorants (e.g., Fe_2O_3) produces metallic effects.

A) Interference colors; B) Combination pigments; C) Metallic colors

Titanium Dioxide – Mica. The first multilayer pigments were marketed in the 1960s as TiO_2- coated muscovite micas [588], [596]. Two different processes are used for coating mica in aqueous suspension on a commercial basis:

1. Homogeneous hydrolysis (at 100 °C)

$$TiOSO_4 + \text{mica} + H_2O \rightarrow TiO_2 - \text{mica} + H_2SO_4$$

2. Titration

$$TiOCl_2 + 2\,NaOH + \text{mica} \rightarrow TiO_2 - \text{mica} + 2\,NaCl + H_2O$$

The pigments are then dried and calcined at 700 – 900 °C. The titration (chloride) process is preferred for interference pigments with thick TiO layers because it is easier to control.

Chemical vapor deposition in a fluidized bed has also been proposed [618] (> 100 °C):

$$TiCl_4 + 2\,H_2O + \text{mica} \rightarrow TiO_2 - \text{mica} + 4\,HCl$$

Only the TiO_2 anatase crystal modification is formed on the mica surface. Small amounts of SnO_2 are therefore used to catalyze conversion to the rutile structure with its higher refractive index, brilliance, color intensity, and superior weather and light resistance [587], [588], [589].

The sequence of interference colors obtained with increasing TiO_2 layer thickness agrees with theoretical calculations in the color space [601], [619], [620]. An experimental development of $L^*a^*b^*$ values is given in [587] (see also ⟶ Dyes, General Survey).

TiO_2 – mica pigments are used in all color formulations of conventional pigments where brilliance and luster are required in addition to color, i.e., in plastics, coatings, printing, and cosmetics. The major market for silver white pigments (pearl pigments, “white metallic”) is the plastics industry.

Table 42 contains a comparative overview of TiO_2 – mica, basic lead carbonate, bismuth oxychloride, and natural fish silver pigments. Some further physical data are summarized in Table 43.

Table 42. Properties and application of pearlescent pigments [621]

Pearlescent pigment	Advantages	Disadvantages	Main fields of application
Natural fish silver	very low density, high luster, nontoxic, light stable	high price, low hiding power, limited availability	nail lacquers
Basic lead carbonate	very high luster, good hiding power, low price, light stable	high density, limited chemical and thermal stability, toxic	buttons, bijouterie
Bismuth oxychloride	very high luster, good hiding power, nontoxic	limited light stability, high density	decorative cosmetics, buttons, bijouterie
Titanium dioxide – mica	high luster, good hiding power (dependent on particle size), highest chemical, mechanical, and thermal stability, nontoxic, low price, low density	inferior luster compared to top qualities of basic lead carbonate and bismuth oxychloride	plastics, lacquers, cosmetics, printing inks, ceramic products

Table 43. Technical data of pearlescent pigments

Pearlescent pigment	Shape	Particle size, µm	Thickness, nm	Density, g/cm^3
Natural fish silver	needles, longish platelets	10 – 40	40 – 50	1.6
Basic lead carbonate	hexagonal crystals	4 – 20	40 – 70	6.4
Bismuth oxychloride	flat tetragonal-bipyramidal crystals	5 – 30	100 – 700	7.7
Titanium dioxide – mica	platelets	1 – 200	200 – 500	3

Iron Oxide – Mica. Like titanium dioxide, iron(III) oxide is suitable for coating mica platelets. It combines a high refractive index (metallic luster) with good hiding power and excellent weather resistance.

Commercial Fe_2O_3 – mica pigments are produced by precipitation of iron(II) or iron(III) ions in aqueous mica suspensions and calcination of the resulting coated particles at 700 – 900 °C [585], [587-589]:

$$2\,FeCl_3 + \text{mica} + 3\,H_2O \rightarrow Fe_2O_3 - \text{mica} + 6\,HCl$$

It is also possible to produce iron oxide – mica pigments by a direct CVD fluidized bed process in which iron pentacarbonyl is oxidized and Fe_2O_3 is deposited on the mica surface (⟶ Iron Compounds – Carbonyl Iron Oxide.) [622].

Independent of the synthesis route, iron(III) oxide crystallizes in the α-modification (hematite) after calcination. Brilliant, intense colors are obtained with 50 – 150 nm layers of Fe_2O_3 (hematite) on muscovite (see Fig. 51 C). Absorption and interference colors are produced simultaneously and vary with layer thickness. The red shades are especially intense because interference and absorption enhance each other. An intense green – red flop with different viewing angles is possible at a Fe_2O_3 layer thickness producing green interference (Section Optical Principles) [623].

Combination Mica-Based Pigments. Simple blending of transparent absorption pigments with pearlescent pigments is only one way to attain new coloristic effects. It is possible to produce nacreous pigments coated with a layer of transparent absorption colorant to realize more pronounced brilliant colors with a sharper color flop. An additional advantage of such pigments is the elimination of dispersion problems associated with transparent absorption pigments due to their small particle size and high surface area.

One possibility for attractive combination pigments is the coating of TiO_2 – mica pigments with an additional layer of an inorganic or organic colorant. The thickness of the TiO_2 layer is decisive for the brilliance or interference effect under regular viewing conditions, whereas the transparent colorant dominates at all other viewing angles (Fig. 52). A deep, rich color with a luster flop at all angles is attained when the colorant and interference color are matched. If the interference color and the mass tone of the colorant are different, a color flop (two-tone pigments) is seen in addition to the luster flop.

Figure 52. Combination pigment consisting of TiO_2 – mica coated with an additional layer of an absorption colorant

Under regular conditions (A), a brilliant color effect dominated by thin film reflection is visible. All other viewing angles (B) show the color of the transparent absorption colorant (Section Transparent Pigments).

Iron(III) oxide is the most important metal oxide for combination with titanium dioxide on mica flakes. Brilliant golden pigments result which can be applied for several purposes. Two routes are used to synthesize these pigments, and different structures are formed [585], [587-589]. In the first, a thin layer of Fe_2O_3 is coated onto the surface of a TiO_2 – mica pigment. The overall interference color is the result of both metal oxide layers. The mass tone is determined by the Fe_2O_3 layer, and interesting gold pigments (e.g., reddish gold) are possible. In the second case, co-precipitation of iron and titanium oxide hydroxides on mica particles followed by calcination leads to greenish gold pigments. Interference and mass tone can be explained as above. The mass tone in this case is, however, further modified due to the additional formation of the highly refractive yellowish iron titanate phase Fe_2TiO_5 (pseudo-brookite) [624].

Other inorganic colorants used instead of iron oxide for combination pigments are Cr_2O_3 (green), iron blue, cobalt blue, Fe_3O_4 (black), and carbon black. In the case of the two black colorants, the interference color is seen as the mass tone. There is an analogy to blends with black pigments in a color formulation, where the transmitted part of the light is absorbed.

Coating of TiO_2 – mica with an organic colorant for a mass-tone or two-tone pigment is performed by precipitation or deposition on the mica pigment surface in aqueous suspension, assisted by complexing agents or surfactants. Another method is to fix the colorant as a mechanically stable layer by using proprietary additives.

4.3.1.6. *New Developments*

Coloristic Variations on the Basis of Mica. Mica platelets can be coated with a variety of compounds to produce novel pigments. Solid-state reactions and CVD processes extend the possibilities for the synthesis of mica pigments. In addition, the calcination of the materials in the presence of inert (e.g., N_2, Ar) or reactive gases (e.g., NH_3, H_2, hydrocarbons) allows the formation of phases which are not producible by working in air. Table 44 contains a summary of nacreous mica pigments with special coloristic properties.

Table 44. Examples for mica-based pearlescent pigments with special coloristic properties

Pigment composition	Preparation	Remarks	Refs.
TiO_{2-x} – TiO_2 – mica	TiO_2 – mica + H_2 (Ti, Si), T > 900 °C (solid-state reaction)	gray, blue-gray	[625]
TiO_xN_y – TiO_2 – mica	TiO_2 – mica + NH_3, T > 900 °C (solid-state reaction)	gray, blue-gray	[622]
$FeTiO_3$ – TiO_2 – mica	Fe_2O_3 – mica + H_2 ,T > 600 °C (solid-state reaction)	gray (ilmenite pigments)	[626]
Fe_3O_4 – mica	Fe_2O_3 – mica + H_2 $T \approx 400$ °C (solid-state reaction)	black	[627]
	Fe^{2+} + O_2 + mica (precipitation)	black	[627]
	$[Fe(CO)_5]$ + O_2 + mica (CVD process)	black	[622]
TiN – mica	$TiCl_4$ + NH_3 + mica (CVD process)	gold	[597]
TiO_2 – C – mica	$TiOCl_2$ + C + mica (precipitation), calcination under N_2	silver-gray, interference colors (carbon inclusion pigments)	[628]
$BaSO_4$ – TiO_2 – mica	Ba^{2+} + SO_4^{2-} + $TiOCl_2$ + mica (precipitation)	low-luster pigments	[629]
Fe_3O_4 – mica (mica surface only partially coated)	Fe^{2+} + O_2 + mica (precipitation)	transparent colors	[604]

Reduction of suitable aqueous metal salts by electroless plating yields metal-coated mica pigments. They are less expensive than noble metal flakes (Au, Ag) and their brilliant metallic appearance is comparable with that of metallic flakes [587], [588].

Functional Pigments Initially, metal oxide – mica pigments were developed purely for their excellent coloristic properties. Since then, they have also become of interest for functional uses. In coatings with a high content of platelet fillers, an advantageous overlapping roof-tile arrangement is possible that provides close interparticle contact,

barrier effects, and dense covering. The composition and thickness of the oxide layer on the mica surface are always responsible for the physical properties like electrical conductivity, magnetism, IR reflectivity, and laser markability. Table 45 lists data on some functional metal oxide – mica pigments.

Table 45. Functional metal oxide – mica pigments

Pigment composition	Property	Application	Refs.
$(Sn,Sb)O_2$ – mica, $Sn(O,F)_2$ – mica	electrically conductive	conductive flooring, antistatic packaging materials, light-colored primed plastic surfaces which can be electrostatically painted in further coating process, light-colored conducting surfaces for dust reduction under clean-room conditions	[630]
Fe_3O_4 – mica	magnetic	magnetic surfaces	[589], [627]
TiO_2 – mica	IR-reflective	IR-reflecting plastic sheets, e. g., for domed and continuous skylights	[631]
TiO_2 – mica, $(Sn,Sb)O_2$ – mica	laser sensitive	laser marking of plastics, coatings	[628]

New Developments Based on Non-Micaceous Systems The class of single crystal lustrous pigments is not limited to the nonabsorbing types like bismuth oxychloride and basic lead carbonate. Recent developments are absorbing pigments such as platelet-like graphite, laminar phthalocyanines and flaky iron oxides. These flakes consist of pure iron oxide or mixed phase pigments, e. g., $Al_xFe_{2-x}O_3$, $Mn_yFe_{2-y}O_3$, or $Al_xMn_yFe_{2-x-y}O_3$. Hexagonal platelet crystals with a diameter of 5 – 50 µm are grown under hydrothermal or flux conditions (melting) [632], [633]. They can be reduced to the corresponding isomorphous magnetites or used as substrates for additional coating with metal oxides [634].

The hematite platelets show a predominantly metallic effect. Very thin particles with a thickness of 50 – 400 nm display a pale copper gloss, which is indicative of interference. The shade can be varied and the properties of the platelets can be controlled by doping. Al or Mn is incorporated by substitution of Fe in the hematite lattice, and Si is incorporated interstitially [635]. Laminar iron oxide pigments are interesting because of their excellent fastness to light and outdoor exposure and their good mechanical stability. Their main applications up to now are in automotive paints and cosmetics.

Novel developments in nacreous and special effect pigments include the group of comminuted PVD thin films This group includes ground single-layer or multilayer film particles. The production of the film is the first step of the synthesis. In the second step, the film is ground to small platelets. Examples are pigments derived from amorphous or nanocrystalline aluminum or pigments consisting of a sequence of layers. These layers act as transmission filters towards each side; a typical sequence is as follows: a specular metal layer (e. g., Al, Cr), a dielectric layer with low refractive index (e. g. MgF_2), and a semi-transparent metal layer. Such compositions are known as Fabry – Perot structures [636]. The optical effect of these pigments is characterized by a very high gloss with brilliant colors. The pigments show a strong color flop when viewed from different angles. PVD film pigment can be used in the graphics industry, particularly as thin-film security device pigments in security printing [637].

Several development programs are concentrated on the search for substrate- containing systems in which mica is replaced by other platelet-like materials. For example, it is possible to replace mica by kaolin or talc and to produce bright conductive pigments by coating with $(Sn,Sb)O_2$ [638].

New pigments based on transparent silica flakes show extremely strong optical effects different to those of mica pigments [639]. Angle-dependent colors and other effects, achieved by the combination of these SiO_2 flakes with thin titania and/or iron oxide coating layers, have led to a new generation of pearl-luster pigments. They add a new dimension to the existing possibilities of color styling with luster pigments.

Other platelet crystals with a high aspect ratio have been reported for phthalocyanine [640], graphite [641], and 1,4-diketopyrrolopyrroles [642].

The CVD process in a fluidized bed (see Section Metal Oxide – Mica Pigments) is also used for depositing interference Fe_2O_3 layers on aluminum flakes [622] as well as for the formation of titanium nitride on platelet substrates [643] or TiO_2 [644], [645].

Regular scattering of spherical particles (opalescence) of TiO_2 is also now used to generate eye-catching color effects [646], [647].

4.3.1.7. *Uses*

Nacreous and interference pigments are used as colorants or part of color formulations for all applications where traditional pigments are used, but where additional color depth, brilliance, iridescence, color shift (flop), and other spectacular effects are desired [648]. Mica-based pigments dominate; their combination of pearl and interference effects, brilliance, stability, and weather resistance is unsurpassed. Furthermore, they are nontoxic [616].

Nacreous pigments require transparent or at least translucent binders or other carriers. Formulations with other pigments have to take their transparency and color mixing rules into account. Producers specify certain product lines for specific applications on the basis of national regulations and technical considerations. They also provide handling guidelines and base formulas.

Color systems with nacreous pigments can be formulated in four ways [606]:

1. Blending nacreous pigments with other pigments in a single-color formulation
2. Using a two-layer coating system in which the upper coat contains the nacreous pigment and the lower coat contains the hiding absorption or metal effect pigments
3. Using a two-layer system with a transparent absorption color formulation applied on top of a layer containing the nacreous pigment
4. Using a multilayer nacreous pigment consisting of an absorbing and/or iridescent coating applied in a single coat to the substrate in the form of platelets (see Section Metal Oxide – Mica Pigments)

Special care must be taken to ensure parallel alignment of the platelet pigments during application. In plastics formed by injection molding, parallel alignment is hindered by the high viscosity of the polymer melts. Flow lines can be avoided by appropriate die/mold design and surface patterning. In coatings [649], [650] and printing inks [651], proper formulation, rheology control, settling and shrinking of the films on drying result in parallel, stacked alignment of the platelets. In automotive coatings [652] additional surface modification of the pigments is used to increase long-term weather resistance [653-655].

For ceramic applications the pigment is coated with an additional SnO_2 layer to stabilize it against the aggressiveness of the frits at high temperature [656].

Cosmetic applications require specific nacreous and interference pigments that are approved for use by national regulations [657], [658]. Nacreous pigments are not used in cosmetics solely for their optical effects. TiO_2 – mica can be used as a sunscreen because TiO_2 strongly absorbs light in the near UV region [659]. A large variety of surface modifications and additives (e.g., monodisperse, submicron spheres of SiO_2) are used to improve processability, control oil absorption [660], and give a softer skin feel [661].

4.3.2. *Metal Effect Pigments*

Definition. Metal effect pigments consist of flakes or lamellae of aluminum (aluminum bronzes), copper and copper – zinc alloys (“gold bronzes”), zinc, and other metals (DIN 55 943, 55 944; FSO 4618–1).

Physical Principles. The metallic effect is caused by the reflection of light at the pigment surface (see Fig. 47); luster (remission) decreases when the proportion of light scattered by the edges and corners of the pigment particles increases. As the pigment becomes coarser, the proportion of reflected light becomes larger; brilliance, brightness and, in the case of “nonleafing” aluminum pigments, the flop (color change with viewing angle) therefore increase. With finer pigments, the proportion of scattered light is greater; brilliance, brightness, and flop are therefore lower but the hiding power is better.

The metal effect depends not only on particle size and particle size distribution, but also on the orientation of the metal flakes within the coating film, particle shape, the transparency of the binder matrix, and the presence of colored pigments or dyes.

Particle Size Distribution. The particle size distribution is determined by conventional sieving or other methods such as laser granulometry (see Section Fundamental

Aspects : Particle Size).

The required particle size of the pigments depends on the intended use and can vary from a few micrometers (e.g., in offset printing inks), to medium grades of < 25 µm or < 45 µm (e.g., in "metallic" automotive topcoats, gravure and flexographic printing inks), to coarser grades (e.g., in corrosion-inhibiting systems, colorants for plastics), and even up to "spangle" size of several millimeters.

The thickness of the flakes can vary from a hundredth of a micrometer up to approximately one micrometer.

The term shape factor denotes the ratio of the platelet thickness to the platelet diameter.

Production. Metallic pigments were first produced in the Middle Ages when gold leaf was made by hand beating. This was replaced by stamping machines. Metal effect pigments are now usually produced in ball mills, using dry milling (Hametag process) and wet milling (Hall process). Other special production processes are used on a small scale (e.g., production of aluminum foil by vaporization, followed by size reduction).

During the ball milling process, a lubricant is added to prevent cold fusion; it also determines the wetting properties of the metallic pigment, i.e., "leafing" or "nonleafing".

Leafing and Nonleafing.
Leafing pigments float on the surface of paint or printing ink films as a result of high interfacial tension. They form a coherent surface film whose reflective properties depend on the particle fineness. Stearic acid is the lubricant usually used in the manufacture of these products.

Nonleafing pigments are fully wetted by the medium and are distributed uniformly throughout the coating. Colored metallic effects are produced by combining the pigments with transparent pigments or dyes. The nonleafing properties are obtained by using lubricants that consist of branched- chain or unsaturated fatty acids (e.g., oleic acid) or polar substances (e.g., fatty amines).

Commercial Products. Depending on the production method and area of application, the pigments are supplied commercially in powder form or as solvent- containing pastes. Pastes for the paint industry are normally made with white spirit or a mixture of white spirit and solvent naphtha. Special pastes containing mineral oils are produced for offset printing inks, polar solvents are used for gravure and flexographic inks, and plasticizers are used to make pastes for coloring plastics. Stabilized aluminum pastes with water or water-miscible solvents are available for waterborne coating systems [662]. Pigments specially coated with organic (e.g., acrylics) or inorganic materials (e.g., silica) are available for powder coatings.

Uses. Metallic pigments are used to produce metallic or chrome effects and also as functional pigments (e.g., for corrosion protection, as conductive paints, or for protection against electromagnetic radiation).

They are employed in paints and coatings; graphics and printing inks (offset, gravure, flexographic and screen printing, and bronzing); and in plastics (coloration by, e.g., masterbatches, fillers, gel coating techniques, and other coatings).

Other industrial uses of aluminum flake include the building industry (production of aerated concrete) and the chemical industry (e.g., production of titanium dioxide, pyrotechnics, and explosives). Copper powder in flake form is used in the chemical industry (e.g., for phthalocyanine production, for lubricants).

Aluminum pigments are produced by grinding aluminum powder, usually obtained by atomizing molten aluminum. The starting material is mainly aluminum ingots with a purity of 99.5 % (DIN 1712), or pure aluminum (> 99.95 %) for special outdoor applications (acid-resistant grades). For standard specifications, see Table 1 ("Aluminum pigments and pastes").

Aluminum powder forms explosive mixtures with air; the lower explosive limit being ca. 35 – 50 g/cm^3. Dust-free aluminum paste is therefore used in most applications.

Aluminum pigments are mainly produced by wet milling in white spirit. The resulting pigment suspension is usually fractionated, sieved, and filtered on a filter press. The filter cake is mixed with solvents to give the usual commercial consistency with 65 wt % solids. Other solvents may be used instead of white spirit, the choice being governed by the intended application. The white spirit can be removed by vacuum drying and replaced by another solvent if necessary (e.g., for printing inks or coloring plastics).

Aluminum behaves as an amphoteric metal, liberating hydrogen from both alkaline and acid aqueous media. In waterborne paints and coloring systems, special stabilized aluminum pigments are therefore required [662]. Aluminum pigments must not be used with halogen- containing solvents because they react very violently to release hydrogen halides (Friedel – Crafts reaction).

The leafing properties of aluminum pigments can be adversely affected by polar solvents or binders. "Leafing-stabilized" aluminum pigments are available for these applications.

Along with special pigments for modern environmentally-friendly coating systems (e.g., waterborne paints and powder coatings) described above, aluminum pigments coated with colored metal oxides (e.g., iron oxide) have appeared on the market which produce not only reflection but also interference effects [663]. Novel color effects are obtained by combining the metal-oxide- coated pigments with transparent colored pigments.

Aluminum has a very low toxicity (⟶ Aluminum – Toxicology and Occupational Health) and is permitted as a coloring agent (EEC no. E 173, C.I. 77 000). It is also approved by the FDA, § 175 300 (USA).

Copper and Gold Bronze Pigments. Copper and gold bronze pigments (powdered copper – zinc alloys) are usually produced by dry milling. Depending on the alloy composition, the following "natural shades" are produced:

Copper	100 % copper
Pale gold	ca. 90 % copper and 10 % zinc
Rich pale gold	ca. 85 % copper and 15 % zinc
Rich gold	ca. 75 % copper and 25 % zinc

Copper – zinc alloys with a higher zinc content (brass) cannot be ground or formed into flake pigments on account of their brittleness. Controlled oxidation of "natural" bronze powders converts them into "fired" bronze powders. These shades (e.g., English green, lemon, ducat gold, fire red) are produced as a result of interference effects that depend on the thickness of the oxide coating.

Copper and gold bronze pigments are not as colorfast as aluminum pigments because they decompose to produce colored oxides and corrosion products. However, stabilized pigments (e.g., with a silica coating) are also available for critical applications in binders with high acid values or that react with copper or zinc.

The classical fields of application for the gold bronze pigments are the graphics industry (bronzing); printing (offset, gravure, flexographic, and screen printing); and coloring plastics. They are also used in the paint industry for decorative finishes (e.g., dip coatings for candles).

Gold bronze pigments are nontoxic. In Germany they are permitted in food packaging materials provided that they do not lead to contamination of the food. They are also allowed for printing on cigarette paper and filter tips according to the tobacco regulations if the zinc content does not exceed 15 %. Similar regulations apply in the United States and other countries.

Flake Zinc Pigments. Flake zinc pigments are used mainly as high-quality anticorrosive pigments in powder or paste form. Owing to their platelet structure they have a considerably higher surface area than spherical zinc dust particles. They can therefore take up much more binder which produces a more flexible coating film than that obtained with zinc dust. Other advantages include a lower settling tendency, good remixing, and problem-free application onto the precoated surface.

The flake zinc pigments give a considerably brighter, better metallic effect than zinc dust. Their appearance can be further improved by combining them with aluminum pigments or by applying a topcoat based on aluminum pigment.

Another widespread application for flake zinc pigments is the coating of small articles with complex shapes (e.g., screws, steel springs, bolts, rivets) and for special anticorrosive paints (Section Zinc Dust).

4.4. Transparent Pigments

Pigments become transparent in binders when the difference between the refractive index of the pigment (which depends on wavelength) and that of the binder is low, and when the particle size of the pigment is in the range 2 – 15 nm. The decisive factor for transparency is, however, the thickness of the pigment particles in the direction in which the light travels.

In practice, pigment transparency is measured by determining the color difference between a sample of the pigmented system on a black background and the black background itself. The transparency measurement method and the definition of the transparency index are described in DIN 55 988.

In a pigment of given chemical composition, transparency can only be influenced by particle size (i.e., by the size distribution of the primary particles) and is thus dependent on the synthesis conditions. Owing to the small size of the primary particles, the pigments tend to agglomerate. Since agglomeration can only be remedied with great difficulty by mechanical grinding, attempts are made to suppress agglomeration by using additives (e.g., sodium salts of higher fatty acids or alkylamines) during synthesis prior to the separation of the pigment from the suspension. In spite of this, almost all transparent pigments are difficult to disperse. They all have a specific surface area (BET) of > 100 m^2/g.

4.4.1. *Transparent Iron Oxides*

Transparent yellow iron oxide has the α-FeO(OH) (goethite) structure; on heating it is converted into transparent red iron oxide with the α-Fe_2O_3 (hematite) structure. Differential thermogravimetric analysis shows a weight loss at 275 °C. Orange hues develop after brief thermal treatment of yellow iron oxide and can also be obtained by blending directly the yellow and red iron oxide powders.

Production.
Transparent yellow iron oxide [51274-00-1], C.I. Pigment Yellow 42:77 492, is obtained by the precipitation of iron(II) hydroxide or carbonate with alkali from iron(II) salt solutions and subsequent oxidation to FeO(OH). On an industrial scale, oxidation is usually carried out by introducing atmospheric oxygen into the reaction vessel. Important factors for good transparency are high dilution during precipitation, a temperature of < 25 °C during oxidation, and short oxidation times (< 5 h). Oxidation can be carried out under acidic or basic conditions [664], [665]. The best results are obtained by using 6-wt % iron(II) sulfate solutions and precipitation with a 10 wt % solution of sodium carbonate, whereby ca. 85 % of the amount required for complete precipitation is added. The starting material is usually crystalline $FeSO_4 \cdot 7\,H_2O$, obtained as a byproduct from the pickling of iron or in the production of titanium dioxide from ilmenite by the sulfate method (see Section Sulfate Method). In order to improve pigment properties, the suspension is matured for about a day before filtration. It is then filtered, dried, and carefully ground to a powder. The primary particles are needle-shaped and have an average length of 50 – 100 nm, a width of 10 – 20 nm, and a thickness of 2 – 5 nm.

Transparent red iron oxide, C.I. Pigment Red 101:77 491, is obtained by heating the yellow pigment (e.g., in a cylindrical rotary kiln) at 400 – 500 °C (Fig. 53).

Figure 53. Electron micrograph of a transparent red iron oxide pigment (Sicotrans Red 2815)

Transparent red iron oxides containing iron oxide hydrate can also be produced directly by precipitation. A hematite content of > 85 % can be obtained when iron(II) hydroxide or iron(II) carbonate is precipitated from iron(II) salt solutions at ca. 30 °C and when oxidation is carried out to completion with aeration and seeding additives (e.g., chlorides of magnesium, calcium, or aluminum) [666]. Transparent iron oxides can also be synthesized by heating finely atomized liquid pentacarbonyl iron in the presence of excess air at 580 – 800 °C [667], [668]. The products have a primary particle size of ca. 10 nm, are X-ray amorphous, and have an isometric particle form. Hues ranging from red to orange can be obtained with this procedure, but it is not suitable for yellow hues.

Transparent brown iron oxides are produced by precipitating iron(II) salt solutions with dilute alkali (sodium hydroxide or sodium carbonate) and oxidizing with air. Only two-thirds of the precipitated iron hydroxide, oxide hydrate, or carbonate is oxidized. Alternatively, the iron oxides can be produced by complete oxidation of the precipitated iron compounds and subsequent addition of half the amount of the initial iron salt solution and precipitation as hydroxide [669], [670]. However, these products have the composition $FeO \cdot Fe_2O_3$ and are ferromagnetic; they are not of practical importance.

Properties and Uses. As far as resistance to light, weather, and chemicals is concerned, transparent iron oxides behave in a similar manner to the opaque iron oxides (see Section Iron Oxide Pigments). In addition, they show a high UV absorption, which is exploited in applications such as the coloring of plastic bottles and films used in the packaging of UV-sensitive foods [671], [672].

Worldwide consumption of transparent iron oxides is 2000 t/a. They are mainly used in the production of metallic paint in combination with flaky aluminum pigments and in the coloring of plastics for bottles and fibers.

Toxicology. Special toxicological studies on transparent iron oxides have not yet been carried out. The results of opaque iron oxides are applicable, see Section Toxicology and Environmental Aspects.

Trade names and producers include Capelle (Gebroeders Cappelle N.V., Belgium), Fastona Transparent Iron Oxide (Blythe Colours Ltd., UK), Sicotrans (BASF and BASF Lacke+Farben, Germany), and Trans Oxide (Hilton Davis, USA).

4.4.2. *Transparent Iron Blue*

Iron blue [14038-43-8], C.I. Pigment Blue 27:77 520 (Milori blue), also occurs in finely dispersed forms (primary particle size < 20 nm, specific surface area 100 m^2/g) that are more transparent than the conventional iron blue pigments. They are generally produced by the same procedure as the less transparent iron blue pigments (see Section Iron Blue Pigments) but a higher dilution factor is used. The transparency of these pigments is exploited solely in the production of printing inks (illustration gravure). All other properties are described in Section Iron Blue Pigments.

Trade names include Manox Iron Blue (Manox, UK), and Vossen-Blue 2000 (Degussa, Germany). Transparent iron blue pigments are also produced by Dainichiseika (Japan).

4.4.3. *Transparent Cobalt Blue and Green*

Transparent Cobalt Blue. Cobalt blue [1345-16-0] C.I. Pigment Blue 28 : 77 346, is also produced as a transparent pigment by precipitating cobalt and then aluminum as hydroxides or carbonates from salt solutions using alkali. The hydroxides or carbonates are then filtered, washed, dried, and calcined at 1000 °C [673]. It is important to carry out the precipitation with high dilution and to distribute the alkali uniformly throughout the entire reaction volume.

Transparent cobalt blue pigments have the form of small tiles (primary particle size 20 – 100 nm, thickness ca. 5 nm, specific surface area (BET) ca. 100 m^2/g). They are resistant to light and weather and are used in metallic paint, but are of little importance.

Transparent Cobalt Green. Analogous to cobalt blue, a transparent cobalt green spinel, C.I. Pigment Green 19:77 335 can be manufactured. The green and blue transparent cobalt pigments are used as filter materials for cathode ray tubes (CRTs) [674].

4.4.4. *Transparent Titanium Dioxide*

Titanium dioxide can also be prepared with a primary particle size of 10 – 30 nm, and hence shows transparent properties. Microcrystalline titanium dioxide was first mentioned in Japanese patents in 1978.

The use of micro titanium dioxide as a white pigment is limited because its light scattering is very low due to the very small crystal size, which means that the coloring effect of conventional TiO_2 is lost. The physical properties are changed significantly; there is strong UV absorption. Consequently, micro TiO_2 is used as a thermally stable, nontoxic, nonmigratory UV -absorbing additive:

- For cosmetics, mainly for sunscreen formulations because of its effective protection over the UV - A, UV -B, and UV -C spectrum [675]
- For automotive paints, especially in combination with aluminum flakes, giving a pearlescent-like appearance; the color flop depends on the concentration of micro TiO_2 in the formulation [677], [678]
- For clear coats and wood varnishes, where it protects the sub strate by virtue of its UV -absorbing properties
- For improving the UV durability of plastics films, and for protecting UV -sensitive foods in plastics wrapping [676]
- In silicon rubber as a heat stabilizer, as a catalyst for hydrogenation [679] and oxidation [680], and in surface protective films for furniture and optical materials [681]

Microfine TiO_2 is produced mainly in the rutile form by various manufacturing routes:

$$TiCl_4 + 4\,NaOH \rightarrow TiO_2 + 4\,NaCl + 2\,H_2O$$

$$Na_2TiO_3 + 2\,HCl \rightarrow TiO_2 + 2\,NaCl + H_2O$$

$$Ti(OC_3H_7)_4 + 2\,H_2O \rightarrow TiO_2 + 4\,C_3H_7OH$$

The process steps include precipitation, neutralization, filtration, and washing, drying, and micronization. Due its small particle size, transparent titanium dioxide has high photoactivity. To reduce this and to give better weatherfastness, the particles are coated with various combinations of inorganic oxides (e.g., silica, alumina, zirconia, iron oxide) before drying in a similar way to that used for conventional titanium dioxide.

Microfine TiO_2 with predominant anatase structure can be manufactured by flame hydrolysis of $TiCl_4$ at < 700 °C [682]:

$$TiCl_4 + 2\,H_2 + O_2 \rightarrow TiO_2 + 4\,HCl$$

World consumption, estimated at 1300 t/a, is increasing.

Trade names include Titanium Dioxide P 25 (Degussa, Germany), Hombitec RM Series (Sachtleben Chemie, Germany), and Micro Titanium Dioxide MT-Series (Tayca, Japan). Transparent titanium dioxide is also produced by Ishihara (Japan) and Kemira Oy (Finland).

4.4.5. *Transparent Zinc Oxide*

Similar to transparent titanium dioxide, Microparticles of zinc oxide are manufactured by sol – gel processes or precipitation in the presence of protective colloids to limit particle growth [682].

An industrial process operates with solutions of zinc sulfate and zinc chloride in the ratio 1 : 2 [684]. Basic zinc carbonate is precipitated by feeding simultaneously the zinc salt solution and a mixed solution of sodium hydroxide and sodium carbonate into a reactor charged with water. The precipitated product is washed intensively several times and then spray dried. It is used as a UV -shielding additive for cosmetics and paints.

Trade names include Sachtotech Micro-Zinkoxid (Sachtleben, Germany) and Z-cote HP 1 (SunSmart, United States).

1. Introduction [1–11]

The increased consumption of colored organic pigments in recent years far exceeds the increased turnover in the industrial sectors in which they are used. The most important reasons for the disproportionately large increase in pigment consumption include advertising and sales promotion, as well as the identification and differentiation of products in the industrial and domestic sectors. Reliable figures for the production of organic coloring agents are only available for certain countries. In the early 1980s, pigments were estimated to account for ca. 40 % of the overall production of organic coloring agents.

The largest area of use of organic pigments is in graphic printing inks, which consumes 50 % of organic pigment production. Almost 25 % of the organic pigments are used in paints and coatings. The coloring of plastics, including spin dyeing of synthetic fibers, consumes less than 20 % and is also an important area of use. The remaining organic pigments are used in textile printing and a number of smaller sectors, including contactless printing processes, office articles and accessories (e.g., colored pencils, crayons, chalks, and typewriter ribbons), and the coloring of wood, cosmetics, and paper.

Definition. Pigments are defined as inorganic or organic, chromatic or achromatic coloring agents that are practically insoluble in the application medium (DIN 55 943). Dyes are coloring agents that are soluble in the application medium. See also → Pigments, Inorganic

In coloring , the crystalline pigment is applied in the solid state, not in dissolved form, to the medium being colored. Both the chemical and the physical properties of pigments (e.g., particle size, particle-size distribution, special types of surface and specific surface area, crystal modification, and crystal form) are important for their industrial applications.

Pigment fractions may, however, also be soluble, depending on the composition of the system to be colored and processing conditions. Important properties of the pigmented system, especially migration, recrystallization, thermal stability, lightfastness, weather resistance, and coloristic properties, are often decisively influenced by the dissolved pigment fractions.

Many organic pigments and dyes have the same basic chemical structure. The insolubility required in pigments can be obtained by excluding solubilizing groups, by forming insoluble salts (lake formation) of carboxylic or sulfonic acids, by metal- complex formation in compounds without solubilizing groups, and particularly by incorporating groups that reduce solubility (e.g., amide groups).

Classification. Organic pigments can be classified in various ways, the two main criteria being chemical structure and coloristic features. A strict subdivision according to one of these criteria is not possible because of overlap. In this article, pigments are classified largely on the basis of chemical structure. They are broadly divided into azo pigments and nonazo or polycyclic pigments. Azo pigments are by far the largest group, not least because they are generally easy to produce and therefore more economical to use. Polycyclic pigments are synthesized according to many widely varying principles. Both groups of pigments can be further subdivided according to their chemical properties and uses. Characteristic properties and most important uses are given for each of the pigment classes described. Examples have been selected on the basis of technical and industrial importance.

Table 1 lists the trade names and producers of important ranges of organic pigments.

2. Physical and Technical Properties

2.1. General Aspects

Organic pigments have to satisfy requirements that may differ considerably depending on the area of use. These requirements relate not only to obvious coloristic properties such as hue, cleanness or brightness, and tinting strength, but also to many other technical properties that are important for trouble-free application of the pigment or necessary to ensure satisfactory use in the colored medium. Such properties include lightfastness, weather stability, and rheological properties. Pigments must also be resistant to organic solvents that may be present during processing and application. Other components of the colored medium (e.g., resins, plasticizers,

or stabilizers) must not adversely affect coloristic properties of the pigments; attention must also be paid to other fastness properties such as blooming, bleeding, or recrystallization.

Table 1. Producers and trade names of organic pigments

Producer	Trade name
BASF	Azalean, Fanal, Heliogen, Lithol, Macatawa, Paliogen, Paliotol, Saugatuck, Segnale, Sico, Sico Echt, Termosolido
Bayer	Bayplast, Fanchon, Helio, Indofast, Perrindo, Quindo, Thio Fast
Cappelle	Acetanil, Bonitol, Diacetanil
CDF-Chimie	Langdocyal
Ciba-Geigy	Cinquasia, Cromophtal, Horna, Irgalite, Irgazin
Cookson	Dalamar, Heucophthal, Monastral, Naphtanil
Dainichi Seika	Chromofine, Seika Fast
Dainippon Ink	Fastogen, Symuler, Symuler Fast
European Colour plc	Eljon
Hoechst	Hansa, Hostaperm, Novoperm, Permanent, PV, PV-Echt, Reflex, Vulcan, Vulcan-Echt
ICI	Lutetia, Monastral, Monolite, Polymon, Vynamon
Køge	Isol
Sandoz	Graphtol
Sansui Colour	Suimei
Sanyo	Sanyo, Sanyo Fast
Sudarshan	Sudarperm
Sumitomo	Sumicacoat, Sumitone, Sumitone Fast
SUN Chemical	Hancock, Montclair, Muskegon, Radiant, Rangoon
Tosoh Corp.	Rubicron
Toyo Ink	Lionogen, Lionol

The above features are determined not only by the chemical constitution of the pigment but also by its physical properties. The particle size and particle-size distribution of the pigment in the application medium play the most important role in this regard. Decreasing particle size (i.e., increasing comminution) generally leads to

1) Increase in the tinting strength in systems in which the intrinsic light scattering of the pigment can be ignored (e.g., in white reductions)
2) Change of shade and cleanness
3) Increase in transparency and thus a decrease in hiding power
4) Increase in gloss (e.g., in printing inks and coatings)
5) Increase in viscosity and deterioration of flow properties of the pigmented media
6) Reduction of lightfastness and weather stability
7) Deterioration of migration fastnesses
8) Lower resistance to solvents
9) Deterioration of recrystallization stability

Optimization of a specific pigment property is thereby connected with a change in other technical properties. Thus, a pigment developed for a specific field of application always represents a compromise between many coloristic and technical properties. For this reason, several commercial grades of a pigment with different particle-size distributions are generally marketed by producers.

The technical and fastness properties always refer to the complete pigment system, not to the pigment itself. For example, the lightfastness of a given pigment may be outstanding in one medium (corresponding to a figure of 8 on the eight-point wool scale), whereas in another medium it may correspond only to a figure of 2 on the same scale.

2.2. Dispersibility

2.2.1. Pigment Powders

During the production process, pigments associate to form agglomerates and aggregates. When pigments are incorporated in the application medium, these structures must be broken down (i.e., dispersed) as much as possible. Nearly all the above-mentioned, particle-size-dependent application and fastness properties and the economic effectiveness of the pigments are affected by the efficiency of dispersion. Unsatisfactory dispersion of the agglomerates may lead to processing problems, including pitting in the deep drawing of plastic sheets or thread breakage in melt-spun synthetic fibers.

Pigment agglomerates resist disintegration. The ease with which disintegration is effected is called the dispersibility and is one of the most important technical properties of pigments. The rate at which dispersion proceeds is a measure of dispersibility.

The dispersion process itself consists of a number of steps that generally occur in parallel.

These steps include breaking down agglomerates in the pigment powder into smaller particles (smaller agglomerates, aggregates, and individual, e.g., primary particles) [12]. The pigment surface is wetted by the binder constituents, and the particles are distributed uniformly in the entire medium. The resultant pigment dispersion must be stabilized (i.e., particles must not recombine by flocculation, reagglomeration, or other processes).

Depending on the dispersion system (i.e., type of pigment, binder, equipment, and processing conditions), one or another of these stages may occur with difficulty. Whereas wetting of the pigment surface is of only minor importance in coloring thermoplastic materials [e.g., rigid poly(vinyl chloride) PVC], it may be crucial when pigments are dispersed in plastisols (coating pastes) based on the same polymer.

Pigments for special areas of application can be optimized with regard to dispersibility. However, in practice a satisfactory degree of pigment dispersion is sometimes impossible or uneconomical to achieve.

2.2.2. Pigment Preparations

Preparations containing the pigment in an already dispersed form are an alternative to pigment powders. Dispersion is performed not by the pigment user but by the pigment producer or in special plants. Pigment preparations contain a carrier material that is identical to or compatible with the application medium, dispersing agents, etc. and depends on the intended use.

Treatment of pigments with a variety of compounds allows modification of dispersibility and other technical properties. One example is the "resination" of azo pigments. The presence of rosin or other hard resins during azo coupling increases the rate of nucleation and decreases the rate of crystal growth. These processes yield smaller pigment particles with a high transparency that are very important in, for example, multicolor printing.

Other agents produce the desired effect by chemical reaction with the base pigment. An example of this kind of surface- treated pigments is the reaction of diarylide yellow pigments with aliphatic amines to form ketimines and enolates. These derivatives are partially soluble in toluene and aliphatic hydrocarbons (the solvents used in publication gravure printing inks) and thus substantially reduce the viscosity of these media. The development of such pigments permitted the use of modern, high-speed gravure printing presses.

2.3. Crystal Modifications

In a large number of pigments, the molecules in the crystal can be arranged in different ways to form different crystal modifications. These modifications vary widely in coloristic and fastness properties. Unstable modifications are often transformed into thermodynamically stable forms, especially during heating or dispersion in the presence of certain solvents or other compounds. Even in pigment forms with similar coloristic properties, application and fastness properties (e.g., lightfastness and durability) can be considerably altered by these modifications. This should be taken into consideration when such pigments are used in practice.

Examples of the variety of requirements that pigments must fulfill for their most important areas of application are given in Chapter 3.

3. Uses

3.1. Printing Inks

Printing inks are discussed in detail elsewhere (→ Printing Inks). The layers formed with the printing inks are generally extremely thin (e.g., 0.7 – 1.2 μm thick in offset printing) and therefore necessitate the use of pigments with a very high tinting strength. A high pigment concentration is required in the ink, and this can lead to rheological and technical problems during printing, particularly for highly transparent pigments with a small particle size and high specific surface area. The latter is especially problematic in modern, high-speed printing presses. These problems can be reduced or eliminated by chemical modification or physical optimization of the pigments (e.g., with regard to particle-size distribution). The high operating speeds of modern printing presses also require fast-drying inks with good adhesion that allow the printed products to be stacked without deterioration of print

quality. As a result, the pigments and the compounds used for their surface coating must not adversely affect solvent release from the printed ink layers, a requirement that is not always easy to satisfy.

In both offset and letterpress printing, color scales are used in which narrow ranges of hues are specified on the basis of color measurement indices for the basic shades yellow, magenta, and blue [blue-green, e.g., in the European Standard (DIN 16 538, 16 539)]. This is intended to enable reprographic companies and printers to obtain printing inks that produce standard results under standard conditions.

In solvent-based printing inks, pigments must be extremely resistant to the solvents used in the ink during processing, particularly during dispersion, but also during transportation and storage of the inks. Toluene or aliphatic hydrocarbons are used in publication gravure printing inks, whereas ketones and esters are employed in packaging gravure printing inks. Unsatisfactory solvent resistance reduces the tinting strength and changes the shade due to recrystallization and also produces a generally undesirable, reduced transparency in the print.

In certain applications, pigments must also be resistant to the material being printed; one example is the fastness to plasticizers when plasticized poly(vinyl chloride) sheets are being printed. Other properties required in practice include fastness to overcoating, sterilization, and calendering; heat sealability; heat stability; and fastness to solvents or consumer goods (e.g., margarine, butter, or soap).

Fastness requirements are particularly stringent for pigments used in decorative papers that are printed by the gravure or flexographic methods and are used to produce laminated sheets. In addition to good lightfastness in the laminated sheet, the type of resin (melamine or polyester) is particularly important in the selection of pigment. For example, in sheets that are produced from polyesters dissolved in styrene monomer, the pigment must be highly resistant to polyesters and styrene.

3.2. Paints and Coatings

The desired coloristic properties and fastness properties of pigments in paints are governed primarily by requirements placed on the articles to which they are applied. Pigments must also satisfy requirements that are determined by the composition of the application medium, the type and concentration of solvents contained in the latter, and processing conditions.

Because air-drying, medium oil, or long oil alkyd resins generally contain only mineral spirit, aromatic hydrocarbons, and higher alcohols (i.e., solvents that are less aggressive toward pigments), the pigments for paints based on these binder systems can usually be chosen without any restrictions. The situation is different however in the case of stoving (baking) enamels (quite often systems based on melamine – formaldehyde or urea – formaldehyde resins), which undergo polycondensation with other resins (e.g., epoxy, short oil alkyd, or acrylic resins) and harden when baked in an oven. Such systems are used on a large scale in industrial finishes. The paints contain aromatic hydrocarbons (in particular xylene), mineral spirit, alcohols, glycols, esters, ketones, and many other solvents. The fastness properties that depend on pigment solubility (e.g., recrystallization or migration) are largely determined by the particle-size distribution, the processing temperature, and the pigment concentration. The solubility of pigments in the application medium increases with increasing temperature, as does the tendency to bleed into a coat of white paint or paint of another color applied on top of the paint film. For example, when a pigment is baked at 120 °C, bleeding into a white coating does not occur, whereas at 140 or 160 °C the coating is strongly colored. The composition of the paint, the type of solvent used, and the baking conditions are important in this connection.

Blooming of a pigment is another defect that depends on pigment solubility. Here, the pigment gradually crystallizes on the surface of a coating or plastic. The resulting layer of pigment crystals can be removed from the surface of the colored medium by rubbing. Blooming continues, however, and only ceases when a substantial proportion of the pigment has migrated from the pigmented system and crystallized on the surface. The prerequisite for blooming is a supersaturated solution of pigment in the application medium. Such a solution is obtained if

1) The pigmented system is subjected to relatively high baking temperature
2) The pigment dissolves partially or completely at the application temperature, and the amount of dissolved pigment exceeds its solubility at the storage or ambient temperature
3) At least partial supersaturation still exists on cooling.

The field of oven-drying systems has undergone extensive technical development, particularly because of environmental protection requirements and solvent emission. For example, thermoplastic acrylic resin systems contain 75 – 85 vol % solvent in the state of application. The high solvent emissions associated with this industrial paint sector have forced the paint industry to develop systems with lower solvent content. Low-solvent systems such as high-solids finishes (→ Paints and Coatings, Chap. 3.2.), nonaqueous dispersions (→ Paints and Coatings, Chap. 3.6.), waterborne systems (→ Paints and Coatings, Chap. 3.3.→ Paints and Coatings, Chap. 3.5.), powder coatings (→ Paints and Coatings, Chap. 3.4.), and systems cured with UV light or electron beams (→ Paints and Coatings, Chap. 3.7.) have been developed . Each of these systems places special requirements on the pigments used. This is especially true for powder coatings, where systems based on epoxy resins are becoming increasingly important (→ Paints and Coatings, Chap. 3.4.). Powder coatings are produced in a multistage process and are applied by electrostatic spraying or fluidized-bed procedures. On subsequent baking at ca. 180 – 200 °C the binder components melt and sinter, before cross-linking. The rheological properties of the melt and viscosity changes often lead to unsatisfactory wetting of the pigment surface. This results in technical problems (plate-out): after hardening, a surface deposit containing unwetted pigment forms on the surface of the colored paint film. The coating can be wiped off by vigorous rubbing and does not reform, in contrast to blooming. The shade of powder coatings often changes, in some cases considerably, as a result of chemical reactions between pigment and curing agent. These reactions depend on the conditions, temperature, and time used for processing and curing. Fastness properties (e.g., lightfastness) can also be affected. Changes of hue are not restricted to specific classes of pigments but occur even in pigments that otherwise have a high fastness level (e.g., quinacridones and dibromoanthanthrone). These difficulties can be reduced or eliminated by using appropriate combinations of pigment and curing systems.

In the paint sector a great deal of interest exists in pigments that may be regarded as extreme cases in relation to their physical properties, e.g., particle size. Such organic pigments include those with high transparency or high hiding power. The first group consists of very small particles and is used mainly for metallic finishes on automobiles. The pigments must have good rheological properties, high lightfastness, high durability, outstanding stability to solvents used in the paint systems, and thus also stability to bleeding and blooming. These requirements are often difficult to satisfy because of the relationships between technical properties and particle size.

Pigments with optimal hiding power are obtained by special finishing processes (e.g., by heating in solvents or water, if necessary under pressure). The pigments consist of very coarse particles: their specific surface area is 10 – 25 m^2/g, in contrast to conventionally treated grades, which have a specific surface area of 50 – 100 m^2/g. The mean particle size calculated from the particle-size distribution is ca. 0.2 – 0.5 µm, compared with 0.03 – 0.2 µm for conventional pigments. The considerably improved rheological behavior of paints produced with such opaque pigments enables the pigment concentration and thus the opacity to be increased further.

3.3. Plastics

In the plastics field, required pigment properties are largely determined by the type of plastic being colored. Organic pigments are difficult to disperse in plastics. The need for more economical plastics processing has led to the development of faster-output machines with higher processing temperatures and lower residence times. The conditions for pigment dispersion are thus particularly unfavorable. Although an unsatisfactory degree of dispersion rarely results in production faults or malfunctions, it does re-

duce process economy. For this reason, pigment preparations in which the pigment is already present largely in dispersed form are generally used to color plastics.

In some polymers (e.g., plasticized PVC), requirements concerning fastness to migration are of paramount importance and are concerned primarily with bleeding and blooming of the pigments. On bleeding, the pigment first dissolves in the application medium and then migrates to an identical or similar medium that is in contact with it. In the case of plasticized PVC, bleeding is attributed to solubility of the pigment in the plasticizer. Accordingly, the bleeding tendency and degree depend on the nature and concentration of the plasticizer and the pigment. Similar considerations also apply to blooming (see Section 3.2), which increases with processing temperature. Limiting concentrations for pigments in a given system are often known, above or below which blooming occurs. As with baking enamels, this concentration range also increases with increasing temperature.

Pigments that bloom always bleed. Pigments, that bleed do not, however, necessarily bloom. The chemical composition of pigments is also a decisive factor in migration (i.e., bleeding and blooming). Attempts are being made to produce migration-fast pigments by increasing molecular size, converting molecules containing acid groups into the corresponding metal salts (so-called pigment lakes or introducing functional groups (e.g., carbonamide groups).

Pigments must be extremely thermally stable in certain plastics. Plastics (e.g., polypropylene and polycarbonate) may be processed at temperatures as high as 320 °C for a few minutes. Lack of heat stability of a pigment or pigmented system is generally associated with a change in hue, but in many cases also with a change in fastness. Poor heat stability may be due to thermal decomposition of the pigment, dissolution of the pigment in the application medium, or changes in the physical properties of the pigment (e.g., particle-size distribution or crystal modification).

Migration does not occur in plastics whose glass transition temperature far exceeds room temperature (e.g., polystyrene or polymethacrylates). The pigments cannot crystallize or bloom even from supersaturated dye solutions. Pigments that are otherwise regarded as being only poorly fast to solvents and that migrate into other polymers may therefore be used for such plastics.

Requirements placed on pigments used for the spin dyeing of synthetic fibers are similar in many respects to those used for coloring plastics. In contrast to textile dyeing methods, in spin dyeing the material (polymer) is colored before the fibers are produced. Lightfastness, heat stability, and fastness to solvents are thus the most important requirements. In all spin dyeing methods the requirements for good dispersibility are particularly stringent. The particle or agglomerate size of the pigments must not exceed ca. 2 μm (i.e., one-tenth of the fiber diameter). Coarser particles decrease the tensile strength of the fiber and frequently cause the fiber to break, particularly during stretching. Because ensuring a sufficient degree of dispersion is very difficult in practice, the use of pigment preparations is often unavoidable in spin dyeing.

In dyeing polyamide fibers, chemical stability of the pigments with respect to the strongly reducing medium of the polyamide melt is also necessary during the polymerization process. Some polycyclic pigments such as phthalocyanine blue, phthalocyanine green, or quinacridones satisfy these requirements.

3.4. Other Uses

Organic pigments are used to color a large number of materials other than those described in Sections 3.13.23.3. The requirements are generally concerned with the solvent resistance necessary for production and processing, and the fastness properties, in particular lightfastness, needed in the end product.

Uses include coloring wood, paper, office articles and accessories, and artists' colors and drawing materials (e.g., colored pencils, wax crayons, chalk, and watercolors), as well as coloring cosmetics, mainly soap.

Textile printing is another important application of organic pigments and is normally considered separately from graphic printing. Pigment requirements in this sector are mainly governed by the end product – the printed textile – and its desired fastness properties (→ Textile Printing).

4. Azo Pigments

Azo pigments contain one or more azo groups −N=N− as the chromophore (**1**):

Residues A and B must not contain pigment-solubilizing groups, such as $-SO_3H$ or longer-chain alkyl groups (see Section 4.5), however.

The pigments are termed monoazo, disazo, trisazo, etc., depending on the number of azo groups per molecule. However, it is almost exclusively the monoazo and disazo pigments that are industrially important. The nomenclature of azo pigments is the same as that of azo dyes (→ Azo Dyes).

Although azo pigments can, in principle, be produced in all colors, yellow, orange, red, and brown shades are the most important in practice. Blue and green azo pigments are of little industrial importance, these shades being produced mainly with high-fastness and cheaper phthalocyanine pigments (see Chap. 7 and → Phthalocyanines).

4.1. Production

Although the azo group can be synthesized in many ways, very few methods apart from diazotization and coupling are important (→ Azo Dyes, Chap. 2.). They are used only where azo coupling is impossible (e.g., if the starting compounds are difficult to obtain).

Almost all azo pigments are therefore produced industrially by azo coupling in which an aromatic amine is diazotized and coupled with a suitable component. A relatively small number of diazo and coupling components are combined in a multiplicity of ways to form the basis for all industrially important azo pigments.

4.1.1. Diazotization

Diazotization, discovered by PETER GRIES in 1862, is the reaction of a primary aromatic amine with sodium nitrite in mineral acid solution, in which the amine is converted into the diazonium salt:

$$ArNH_2 + 2\,HY + NaNO_2 \longrightarrow Ar{-}N{\equiv}N^+Y^- + NaY + 2\,H_2O$$

Ar = aryl; Y = Cl, HSO_4

In industrial diazotization, one equivalent of an aromatic amine is generally dissolved in 2.5 – 3 equivalents of hydrochloric or sulfuric acid and then reacted at 0 – 5 °C with one equivalent of aqueous sodium nitrite solution. Weakly basic amines require larger amounts of more concentrated acid. Often such diazotizations can only be carried out with nitrosylsulfuric acid (HSO_4NO) in sulfuric acid.

Details of the mechanism and types of diazotization can be found elsewhere (→ Azo Dyes, Chap. 2.1.1.).

Aromatic diamines can be doubly diazotized (bisdiazotization). The term tetrazotization, although still used for this reaction, is incorrect and should not be employed.

Substituted anilines are generally the most suitable diazo components for azo pigments. The substituents confer many important properties on pigment fastness such as hue, solvent and migration lightfastness, and weather resistance. Important substituents include chlorine, methyl, methoxy, ethoxy, nitro, trifluoromethyl, carboxy, and carbalkoxy groups. Diazo components for producing azo pigments can be subdivided into five main groups.

1) Substituted aniline derivatives. Examples:

2) Aminobenzamides, aminoanilides, and aminobenzene sulfonamides. Examples:

3) Aromatic diamines. Examples:

4) Polycyclic amines. Example:

5) Heterocyclic amines and diamines. Examples:

Diazonium compounds are often stable only in the cold. Heat, light, and heavy-metal ions accelerate the decomposition of diazonium compounds. Diazotizations are therefore generally performed in rubberized iron vessels, vessels lined with an acid-resistant cladding, or in stirred tanks made of glass-fiber-reinforced polyester, but they may also be carried out in wooden vats.

Because many diazonium compounds are explosive in the solid state, synthesis of the diazonium salt is followed as quickly as possible by coupling in an aqueous medium without intermediate separation of the product.

4.1.2. Coupling

Coupling is the electrophilic substitution of the diazo group for a hydrogen atom on the coupling component to form an azo bond:

$$Ar{-}N{\equiv}N^{+}\ Y^{-} + H{-}R \longrightarrow Ar{-}N{=}N{-}R + HY$$

HR = coupling component

Because free acid is formed in the coupling reaction, the optimum pH for coupling must be maintained by the addition of base. If coupling is performed with amines the optimum pH is 4 – 7, with phenols or naphthols 7 – 9.

General reaction conditions, along with the influences of substituents of the components in azo coupling, are described in detail elsewhere (→ Azo Dyes, Chap. 2.1.2.).

Coupling components for azo pigments are generally sparingly soluble in water and dissolve in strong bases as the naphtholates or enolates. The coupling components can be divided into *N*-acetoacetyl derivatives of aromatic or heterocyclic amines, hydroxynaphthalene derivatives, heterocyclic coupling components, and corresponding bifunctional components. In the following examples the coupling sites are identified by arrows.

***N*-Acetoacetyl derivatives of aromatic or heterocyclic monoamines** (**2**) are represented by the general formula:

2

R = H, Cl, CH_3, OCH_3, OC_2H_5, NO_2, $NHCOCH_3$, or an annealed heterocyclic ring

$n = 1 - 3$

Naphtol AS-IRG

Examples: (see above)

2-Hydroxynaphthalene derivatives, particularly 2-hydroxy-3-naphthoic acid (BON), and their arylamides.
Examples:

β-Naphthol

2-Hydroxynaphthoic acid (BON)

Naphtol AS

Naphtol AS is a trade name registered by Hoechst AG. Analogous pigments from other companies are designated Naphtol AS

Variation of the substituents in the arylamide residue and, to a lesser extent, in the 2-hydroxy-3-naphthoic acid residue of Naphtol AS gives a large number of derivatives that are used as coupling components in azo pigment synthesis, but also play an important role in Naphtol AS developing dyes (→ Azo Dyes, Chap. 6.).
Examples:

Naphtol AS-OL

Naphtol AS-BS

Naphtol AS-KB

Naphtol AS-LC

Heterocyclic Coupling Components Examples:

5-Pyrazolone derivatives
R = CH_3, $COOCH_3$, $COOC_2H_5$
R′ = H, Cl, CH_3

Barbituric acid

R = H, CH_3 R′ = H, Cl

Bifunctional Coupling Components Examples:

Naphtol AS-G

4.1.3. Special Features of Azo Pigment Synthesis

Whereas azo dyes generally must be salted out from the aqueous reaction solution after synthesis, azo pigments precipitate during synthesis as almost insoluble substances and are thus virtually impossible to purify subsequently. Particular attention must therefore be paid to the quality of the starting products used for the synthesis of azo pigments.

After diazotization, amines often form water-soluble diazonium salts, whereas the coupling components used for azo pigments are almost insoluble in water. Although they generally dissolve in alkali, the pH value is then too high for coupling. The alkali solution of the coupling component is therefore normally reprecipitated in the cold with acid (e.g., acetic or hydrochloric acid), if necessary with the addition of a dispersing agent. The coupling component thus becomes very finely suspended in water and can couple readily and smoothly with the dissolved diazonium salt.

Acid formed during azo coupling can be buffered by the sodium acetate formed on precipitation of the coupling component (see above). Otherwise dilute alkali must be added continuously during coupling to maintain a constant pH. Sodium phosphates, calcium carbonate, or magnesium oxide can be added as a buffer instead of sodium acetate.

The outcome of azo pigment synthesis may be influenced by the following parameters:

1) Type of coupling (i.e., the sequence and rate of addition of components)
2) Concentration of reactants
3) Temperature of the reaction mixture
4) Process parameters: shape and size of the reaction vessel, stirrer, design and stirring rate

Extremely small pigment particles usually remain after coupling. The drying of pressed pigment cakes after filtration and washing generally results in association of the pigment crystallites because of their high surface energy. In many cases the resulting agglomerates and aggregates cannot be satisfactorily comminuted even after intensive grinding. Optimum comminution is, however, a prerequisite for the use of a pigment, for both technical and economic reasons.

Azo coupling is therefore followed by "preparation" or thermal after treatment ("finishing") of the pigment. In the former, the pigment particles are coated with various substances (e.g., resins or plastic dispersions) during or after synthesis to prevent, or at least counteract, their reagglomeration.

With thermal after treatment, the pigment suspension may simply be heated for a few hours at 60 – 100 °C or higher. Often, however, the pressed filter cake is first washed, reformed into a paste, and then aftertreated at 60 – 100 °C. Very sparingly soluble pigments are treated in organic solvents (e.g., alcohols, glacial acetic acid, chlorobenzene, 1,2-dichlorobenzene, dimethylformamide). Preparation or finishing produces better-formed crystals and a narrower particle-size distribution, and therefore improves pigment dispersibility.

In conclusion, crystal physics are important in pigment synthesis. Once the insoluble pigment crystallites have been formed during synthesis, chemical influences no longer play a role. Only physical parameters such as crystal shape, crystal size, crystal quality, and particle-size distribution can subsequently be altered.

The apparatus used for the industrial synthesis of azo dyes (→ Azo Dyes, Chap. 2.5.) can also be used for the synthesis of azo pigments. For pigments requiring thermal after treatment, a pressure-resistant steel vessel with stirrer and connected filter press is necessary so that the crude pressed pigment cake can be made into a paste and heated with stirring (if necessary under pressure).

The industrial synthesis of azo pigments is now illustrated with some examples.

Production of C.I. Pigment Yellow 1, 11 680 [13] (see Section 4.2.1). *Diazotization.* In a diazotization vessel, 912 kg of 3-nitro-*p*-toluidine (4-methyl-2-nitroaniline) is stirred overnight with water. Then 3395 L of 5 mol/L hydrochloric acid is added, together with sufficient ice to lower the temperature to 0 °C. Sodium nitrite solution, 792 L of 40 wt %, is then run in underneath the surface. Any excess sodium nitrite is removed by addition of 3-nitro-*p*-toluidine. Kieselguhr or active charcoal is added as a clarifying agent to the diazonium salt solution, which is then filtered through clarifying filter equipment.

Dissolution of the Coupling Component. Acetanilide (1098 kg) is stirred with water for 1 h at 25 °C; 510 kg of calcium carbonate and 206 kg of 33 % sodium hydroxide solution is then added.

Coupling. The reaction mixture is heated to 33 °C, and the clarified diazonium salt solution is then run in. After 30 min hydrochloric acid is added to adjust the pH to 3 – 4. After an additional 20 min the pigment is separated by filtering the suspension through a filter press and

washed with water to remove salts. The filter cake is dried at 60 – 65 °C. The yield is 2042 kg.

Production of C.I. Pigment Red 112, 12 370 [14] (see Section 4.6). *Diazotization.* In a steel-enamel stirred tank, 500 kg of glacial acetic acid is heated to 65 °C, and 276 kg of 2,4,5-trichloroaniline is added. This solution is run into a mixture of 3500 L of water and 1120 L of 5 mol/L hydrochloric acid. The reaction mixture is cooled to 0 °C by addition of ice and rapidly diazotized with 185 L of 40 wt % sodium nitrite solution. The temperature must not exceed 0 °C. After 2 h, 107 kg of calcium carbonate suspended in water is added. The volume is made up to 8500 L with water; kieselguhr and active charcoal are added, and the solution is filtered through a clarifying filter.

Dissolution of the Coupling Component. At 30 °C, 420 kg of Naphtol AS-D is dissolved in 322 L of 33 % sodium hydroxide and 3000 L of water; 10 kg of kieselguhr is added, and the solution is filtered. The volume is made up to 14 000 L and temperature is 20 °C. Then, 84 g of Igepon T [the condensation product of oleyl chloride with sodium methyltaurine, $H_{33}C_{17}CO(CH_3)N(CH_2)_2SO_3Na$] in 200 L of water is added and the mixture is cooled to 3 °C with ice. The coupling component is precipitated by rapid addition of 235 L of glacial acetic acid.

Coupling. The reaction mixture is heated to 38 °C, and the filtered diazonium salt solution is run in under the surface of the suspension of the coupling component within 3.5 h. After completion of coupling, the pigment is isolated by filtering the suspension through a press, washing to remove salts, and drying at 50 – 55 °C. The yield is 700 kg.

Production of C.I. Pigment Yellow 13, 21100 [15] (see Section 4.3.1). *Bisdiazotization.* 151.8 kg of 3,3′-dichlorobenzidine dihydrochloride (100 %) is added to 2000 L of water and stirred overnight. The next morning 600 L of 5 mol/L hydrochloric acid is added, and the reaction mixture is cooled to −3 °C with ice. Bisdiazotization is performed by rapid addition of 157 L of 40 wt % sodium nitrite solution, whereby the temperature should not rise above 0 °C. Then, 10 kg of kieselguhr is added to the brownish-yellow solution, which is made up to 10 000 L and clarified.

Dissolution of the Coupling Component. Acetoacet-2,4-dimethylanilide, 258 kg, is dissolved in a mixture of 133 L of 33 % sodium hydroxide and 4000 L of water. Part of the acetoacetxylidide is precipitated by the addition of 150 L of 5 mol/L hydrochloric acid; 60 kg of sodium formate and 90 kg of calcium carbonate are then added, and the volume is made up to 8000 L. The temperature is 25 °C.

Coupling. The bisdiazonium salt solution is run in within 2.5 h underneath the surface of the suspension of the coupling component. Stirring is continued for another 30 min, and 200 L of 5 mol/L hydrochloric acid is added to adjust the pH to ca. 3.5. After an additional 30 min stirring, the reaction mixture is heated to 100 °C and held there for 1 h. The reaction mixture is then cooled to 70 °C by adding water; the pH should remain constant at 3.5. The suspension is filtered through a press and the pigment is washed to remove salts. After drying at 60 – 65 °C, 381 kg of pigment is obtained.

4.2. Yellow and Orange Monoazo Pigments

Yellow and orange monoazo pigments include compounds that are produced by coupling diazotized substituted anilines with linear or cyclic compounds containing an activated methylene group (e.g., acetoacetarylides or 1-aryl-5-pyrazolones).

4.2.1. Yellow Monoazo Pigments (Hansa Yellow Pigments)

The most important coupling components in the yellow monoazo pigment class are derivatives of acetoacetylaminobenzene (acetoacetarylides).

The preferred substituents R_K are CH_3, OCH_3, OC_2H_5, Cl, Br, NO_2; for industrially important products, *n* is 0 – 3. The acetoacetarylides are produced by reacting the corresponding aromatic amines with diketene or ethyl acetoacetate.

The yellow monoazo pigments are obtained by diazotizing substituted anilines and coupling them with acetoacetarylides. Their general synthesis is thus represented by **3**. (This designation is conventional in azo dyes and azo pigments. The horizontal arrow between the aromatic amine and the coupling component denotes "by coupling diazotized . . . with . . .").

3

In the most important pigments, R_D and *m* have the same meaning as R_K and *n* (see above). Whereas the first red azo pigments based on β-naphthol as coupling component were marketed around 1900, the first yellow azo pigments with acetoacetarylides as coupling components were discovered by the firm Meister Lucius & Brüning in 1909 (Hansa Yellow). These pigments are still industrially important.

The basic structure of yellow monoazo pigments is generally described in the 2-oxoazo form (**4**),

4

although the 2-oxohydrazone form (**5**), which has thus far been found exclusively in pigments investigated by three-dimensional X-ray structural analysis, probably occurs in reality [16].

C.I. Pigment Yellow 6, 11670 [*4106-76-7*]:

5

Yellow monoazo pigments are very lightfast and resistant to weathering, but only moderately resistant to solvents, overspraying, overpainting, and bleeding. Because they are relatively cheap to produce, some yellow monoazo pigments still are among the most important organic pigments even though they have been known for more than 80 years.

Yellow monoazo pigments are used mainly to pigment coating materials, especially air-drying paints and emulsion paints, as well as in the printing industry where a high recrystallization resistance is not required. These pigments are less suitable for pigmenting plastics because of their unsatisfactory migration fastness.

Examples of industrially important yellow monoazo pigments follow:

C.I. Pigment Yellow 1, 11680 [*2512-29-0*] (for industrial production, see Section 4.1.3)

C.I. Pigment Yellow 3, 11710 [*6486-23-3*]:

Both Pigment Yellow 1 and Pigment Yellow 3 are inexpensive. Pigment Yellow 1 has a medium yellow shade. Pigment Yellow 3 has a strong greenish-yellow shade. They are used in large amounts in almost full-shade ranges in paints.

C.I. Pigment Yellow 74, 11741 [*6358-31-2*] is also a pure greenish-yellow pigment, with a very high tinting strength (the order of magnitude of diaryl yellow pigments). This pigment is therefore also used in the printing ink industry when the better lightfastness of yellow monoazo pigments is required.

C.I. Pigment Yellow 97, 11767 [*12225-18-2*] has an extremely good lightfastness and weather resistance. It also has a much better solvent resistance and fastness to overpainting than the previously described yellow monoazo pigments:

The main difference between Pigment Yellow 97 and other yellow monoazo pigments is the presence of an additional sulfonylaminophenyl group, which is primarily responsible for its better migration fastness. Because of its good fastness properties and clean shade, Pigment Yellow 97 is used on a large scale in artists' colors and industrial paints.

4.2.2. Monoazopyrazolone Pigments

The acetoacetylamino group of the coupling component in yellow monoazo pigments can be replaced by the 5-pyrazolone ring, in which the acetoacetyl group is incorporated into a heterocyclic ring system. When reacted with the same substituted anilines as diazo components, this large conjugated system (**6**) generally yields reddish-yellow pigments.

6

In **6**, R is usually CH_3, $COOCH_3$, or $COOC_2H_5$; X may be H, CH_3, or Cl; R_D is defined in the same way as R_K (see Section 4.2.1).

Despite their extremely good lightfastness in full shades and high tinting strength, monoazopyrazolone pigments are no longer important, primarily due to their unsatisfactory solvent resistance and migration fastness.

C.I. Pigment Yellow 10, 12710 [*6407-75-6*] still has some economic importance, however, particularly in the United States where it is used for road-marking paints:

4.3. Disazo Pigments

Disazo pigments are divided into two structural types, depending on whether a bifunctional diazo component or a bifunctional coupling component is used.

Disazo pigments with *bifunctional diazo components* (diamines) are obtained by bisdiazotization of a diamine $H_2N-A-NH_2$ and subsequent coupling with two equivalents of coupling component. These pigments are also termed *diarylide pigments* and are represented by general formulas **7** and **8**:

7
Yellow

8
Orange, red
A = diphenyl residue

where R_K has the same meaning as in Section 4.2.1; X may be H, CH_3, or Cl.

Disazo pigments with *bifunctional coupling components* are obtained by coupling two equivalents of a diazotized amine $A-NH_2$ with one equivalent of a bisacetoacetylated diamine $H_2N-B-NH_2$. Disazo pigments are also called *bisacetoacetarylide pigments:*

B = phenylene or diphenylene residue

4.3.1. Diarylide Pigments

Diarylide pigments are extremely important economically, particularly in the production of printing ink. They generally have structure **9**:

9

R = Cl, CH_3, OCH_3; R′ = H or R = R′ = Cl

3,3′-Dichlorobenzidine is by far the most important bisdiazo component.

The term "benzidine pigments" is still sometimes used for this group, but it is incorrect because benzidine has never been used to produce diarylide pigments.

Diarylide pigments are produced by the bisdiazotization of 3,3′-dichlorobenzidine, followed by coupling with two equivalents of an acetoacetic arylide (example in Section 4.1.3).

Because of their large molecular size, diarylide pigments are considerably more resistant to solvents and recrystallization than monoazo pigments. Because they contain more conjugated double bonds they have a substantially higher tinting strength but a lower lightfastness (although this is usually satisfactory for most applications).

Examples of industrially important diarylide pigments follow:

C.I. Pigment Yellow 12, 21090 [*6358-85-6*] (**10**) is an extremely important diarylide pigment with one of the largest organic pigment sales volumes.

10

C.I. Pigment Yellow 13, 21100 [*5102-83-0*] (**11**) has an even higher tinting strength and better lightfastness than Pigment Yellow 12, good solvent and recrystallization resistance, and a shade complying with the European standard for three- and four- color printing. The production of Pigment Yellow 13 is described in Section 4.1.3.

11

Both *C.I. Pigment Yellow 14, 21095* [*5468-75-7*] (**12**) and *C.I. Pigment Yellow 17, 21105* [*4531-49-1*] (**13**) are important greenish-yellow pigments.

Y = CH_3: **12**
Y = OCH_3: **13**

These too may be regarded as typical printing ink pigments and are suitable for all printing processes. Pigment Yellow 13 and Pigment Yellow 17 are also used to color plastics.

If 2,2′,5,5′-tetrachlorobenzidine is used as the bisdiazo component instead of 3,3′-dichlorobenzidine, the hue is displaced toward greenish yellow. An important example is *C.I. Pigment Yellow 81, 21127* [*22094-93-5*] (**14**):

14

The solvent fastness of diarylide pigments and the resulting technical properties (e.g., fastness to blooming and fastness to overspray) are considerably superior to those of monoazo pigments. The lightfastness and weather resistance of most disazo pigments are, however, generally not sufficient for use in paints. Exceptions include Pigment Yellow 81 (**14**) and, in particular, *C.I. Pigment Yellow 83, 21180* [*5567-15-7*] (**15**):

15

Pigment Yellow 83 is a reddish-yellow pigment of high tinting strength that is used because of its good technical properties in graphic

printing and in coloring coating materials and plastics.

Pigment Yellow 81 is also suitable for coloring plastics. Pigment Yellow 13 (**11**) and Pigment Yellow 17 (**13**) have good tinting strengths but are less lightfast; they are used as pigments in inexpensive plastic articles.

Two disazopyrazolone pigments are of particular industrial importance, namely, *C.I. Pigment Orange 13, 21110* [*3520-72-7*] (**16**) and *C.I. Pigment Orange 34, 21115* [*15793-73-4*] (**17**).

Y = H: **16**
Y = CH_3: **17**

Pigment Orange 13 (**16**) has a considerably more yellowish shade and is somewhat less lightfast than Pigment Orange 34 (**17**). Both pigments are used on a large scale in the graphics industry for all conventional printing methods. In addition, they are used in the plastics industry when less stringent fastness properties are required.

4.3.2. Bis(*N*-acetoacetarylide) Pigments

Of the bis(*N*-acetoacetarylide) pigments, *C.I. Pigment Yellow 16, 20040* [*5979-28-2*] (**18**) has the greatest industrial importance (see below).

Pigment Yellow 16 is produced by coupling two equivalents of diazotized 2,4-dichloroaniline with bisacetoacetylated *o*-toluidine (Naphtol AS-G). The pigment has a medium-yellow shade and is particularly suitable for paints because of its good fastness to blooming and overspray. It is also used in printing inks and plastics.

18

4.4. *β*-Naphthol Pigments

β-Naphthol pigments contain 2-hydroxynaphthalene (*β*-naphthol) as coupling component and anilines that are substituted mainly in the 2- or 4-positions as diazo components. Their general formula is:

$R^2 = R^4$ = H, Cl, NO_2, CH_3, OCH_3, OC_2H_5

Like the Hansa Yellow pigments, *β*-naphthol pigments probably occur in the *o*-quinonehydrazone and not the hydroxyazo form (see Section 4.2.1). This was first demonstrated for *C.I. Pigment Red 1, 12070* [*6410-10-2*] (**19**) by three dimensional X-ray structural analysis [17]:

19

Crystal structure determinations subsequently carried out on Naphtol AS pigments gave similar results. All hitherto investigated pigment molecules are almost completely planar [18].

Azo compounds based on *β*-naphthol are among the oldest known synthetic dyes. However, *β*-naphthol pigments, such as C.I. Pigment Red 1 (**19**, Para Red), were first produced more than a century ago. Para Red was first used in "ice colors" as a developing dye for cotton (see → Azo Dyes, Chap. 6.1.1.1.). Subsequently, the compound was also produced by coupling in the presence of a carrier material and, finally, in the form of the pure substance as a pigment (Paratoner). The pigment is now used to only a limited extent, mainly for coloring inexpensive coating materials. Today only a few straight *β*-naphthol pigments (i.e., which have not been converted into lakes) are industrially important;

those that are used, however, are employed in large amounts.

The solvent resistance and migration fastness of these pigments are poor. Because of their clean hues, good lightfastness, weather resistance, and relatively low cost, *C.I. Pigment Red 3, 12120* [*2425-85-6*] (**20**, Toluidine Red) and *C.I. Pigment Orange 5, 12075* [*3468-63-1*] (**21**, Dinitraniline Orange) are among the most important organic pigments.

20

21

Both pigments are used mainly in the full-shade range to color coating materials. Grades of Pigment Red 3 (**20**) with a yellowish-red to bluish-red hue are commercially available. Pigment Orange 5 (**21**) is also used on a moderately large scale in the printing ink industry.

4.5. Azo Pigment Lakes

Azo pigment lakes are based on monoazo dyes having sulfonic acid groups. These soluble dyes are converted into insoluble pigments by salt formation (lake formation) with metal ions (e.g., from sodium, calcium, strontium, barium, or manganese salts). In the following formulas, the symbol M denotes metal ions. The lakes are divided into β-naphthol pigment lakes and 2-hydroxy-3-naphthoic acid (BON) pigment lakes.

4.5.1. β-Naphthol Pigment Lakes

Coupling a diazotized aniline sulfonic acid with β-naphthol yields a monoazo dye that is converted to the pigment by lake formation. The sodium salt of β-naphthol is coupled in an alkaline medium and then reacted with an alkaline-earth or manganese salt.

The first pigment of this series, a coupling product of 1-naphthylamine-2-sulfonic acid and β-naphthol (Lithol Red), was patented in 1899 by Julius (BASF). The sodium, barium, and calcium salts, which were initially precipitated on a carrier but were subsequently used as pure products, proved to be valuable pigments for the printing ink industry because of their insolubility.

Many β-naphthol pigment lakes were developed, but very few are still used today. Some of them are, however, of considerable industrial importance. Examples include the following:

C.I. Pigment Red 49, 15630 (**22**, Lithol Red, [*1103-38-4*] for M = Ba) and *C.I. Pigment Red 53, 15585* (**23**, Lake Red C, [*5160-02-1*] for M = Ba).

22

23

These pigments (M is usually barium) are particularly important for printing inks. Although Pigment Red 49 (**22**) is still produced on a large scale, particularly in the United States, its importance is decreasing. Pigment Red 53 (**23**) exists in both transparent and an opaque forms, depending on the method of production and the additives used (e.g., rosin soaps). The barium lake has a medium-red shade. Because of its high tinting strength and solvent fastness the pigment is used on a large scale in printing processes (i.e., for letterpress, offset, gravure, and flexographic printing).

C.I. Pigment Red 68, 15525 (Ca) [*5850-80-6*] is a clean yellowish-red pigment. Although only moderately lightfast, it is extremely heat stable, which makes it particularly suitable for pigmenting plastics (e.g., PVC or polyolefins).

Production of C.I. Pigment Red 53:1, 15585:1 [*5160-02-1*] [19]. *Diazotization.* 487.3 kg of 4- chloro-3-methylaniline-6-sulfonic acid (CLT acid) is stirred overnight with a mixture of 3000 L of water and 114 kg of hydrochloric acid (calculated as 100 %). The next morning, the reaction mixture is cooled with ice

to 15 °C and the volume is made up to 10 000 L. Then, 288.6 L of 52.6 wt % sodium nitrite solution is run in beneath the surface within 3 h. The temperature is maintained at 15 – 18 °C; the final volume is 12 000 L.

Dissolution of the Coupling Component and Coupling. 158.4 kg of sodium hydroxide is dissolved in 4000 L of water at 20 °C; 326 kg of β-naphthol is then added. After ca. 20 min at 20 °C, all the naphthol has dissolved. The volume is made up to 9000 L, and the diazonium salt solution is run into the sodium naphtholate solution within 1 – 5 min. The reaction mixture is stirred for 1 h, and a mixture of ca. 50 – 55 kg of acetic acid and 300 L of water is added to neutralize the reaction mixture. The mixture is checked for a pH of 7 and for the absence of diazonium salt, and is stirred for 2 h. It is then filtered and washed with the last quarter of the mother liquor (if at all). About 440 kg of the pressed filter cake is stirred overnight with 4000 L of water. The suspension is then diluted with 7000 L of water and stirred overnight. The resulting suspension is allowed to flow into boiling barium chloride solution prepared from 14 000 L of water, 580 kg of sodium chloride, and 175 kg of barium chloride in a stirred tank. Addition lasts ca. 1.5 h. The temperature is then maintained for another hour at 102 – 104 °C. The suspension is filtered through a press, and the pigment is washed with mother liquor and dried at 70 °C. The yield is 550 kg.

4.5.2. 2-Hydroxy-3-naphthoic Acid Pigment Lakes (BON Pigments)

The BON group of pigments consists of monoazo pigment lakes in which 2-hydroxy-3-naphthoic acid (beta-oxynaphthoic acid, BON) is the coupling component. In this case too, aromatic amines, mainly those with a sulfonic acid group in the 2-position to the amino group, are used as diazo components. The BON pigments are more lightfast than β-naphthol pigments and have a more bluish-red shade (Rubine).

The pigments are preferably calcium or barium salts. Manganese lakes, which are generally more lightfast than the corresponding alkaline-earth salts, are most important in the paint industry but are also used in printing inks. They are seldom used for plastics, primarily because manganese catalyzes the oxidative decomposition of some plastics.

C.I. Pigment Red 57:1, 15850:1 [*5281-04-9*] (Lithol Rubine) is one of the most important organic pigments and an important printing ink pigment:

It is used in almost all printing ink sectors (in letterpress and offset printing, and in illustration and packaging gravure printing) for several reasons. It has a brilliant shade that corresponds to the standard "magenta" shade of the European scale for multicolor, letterpress, and offset printing, as well as high tinting strength, good lightfastness, and solvent resistance.

C.I. Pigment Red 48, 15865 (Permanent Red 2B Pigment) is used in all important areas. It is the calcium or manganese salt of the coupling product formed from 2-amino-4- chloro-5-methylbenzenesulfonic acid and 2-hydroxy-3-naphthoic acid:

M = Ca: Pigment Red 48:2 [*7023-61-2*]
M = Mn: Pigment Red 48:4 [*5280-66-0*]

The manganese lake in particular is used for air-drying paints and stoving enamels because of its good lightfastness and fastness to overpainting.

C.I. Pigment Red 52, 15860 (BON Lake Red C) is also used in the graphics industry, mainly in the United States.

M = Ca: Pigment Red 52:1 [*17852-99-2*]
M = Mn: Pigment Red 52:2 [*12238-31-2*]

4.5.3. Other Pigment Lakes

In addition to the two groups of pigment lakes discussed in Sections 4.5.1 and 4.5.2, some acetoacetic arylide and Naphtol AS pigment lakes are also available that are used mainly to pigment plastics because of their good migration fastness. An example is *C.I. Pigment Yellow 61, 13880* (R = H) [*12286-65-6*]:

The pigment has a clean shade with a greenish-yellow hue, good lightfastness and weather resistance, and a particularly high thermal stability. It can be used to color PVC and polyolefins.

C.I. Pigment Yellow 62:1, 13940:1 (R = CH_3) [*12286-66-7*] has similar uses.

C.I. Pigment Red 151, 15892 [*61013-97-6*] is a bluish-red pigment that is used, among others, for pigmenting PVC and polyolefins. This pigment also has excellent heat stability:

4.6. Naphtol AS Pigments

In Naphtol AS pigments, the anilide of 2-hydroxy-3-naphthoic acid (trade name: Naphtol AS) and its substitution products are used as coupling components. They have the following general structure:

Some important substituents are R = CH_3, OCH_3, OC_2H_5, Cl, Br, NO_2, $NHCOCH_3$; R′ = R, $COOCH_3$, $CONHC_6H_5$; *m, n* = 0 – 3.

This type of pigment achieved initial popularity in the form of developing dyes for cotton (→ Azo Dyes, Chap. 6.1.1.2.). In this group of dyes, 2-hydroxy-3-naphthoylaniline (Naphtol AS) was first used as a coupling component instead of β-naphthol in 1911. The sodium salt of Naphtol AS is absorbed by cellulose fibers due to its substantivity. By "development" with diazo components (coupling), high colorfastness is obtained. Insoluble colorants (i.e., pigments) are thus formed on the fiber. The discovery of Naphtol AS pigments was patented as early as 1911. Naphtol AS and many derivatives with a substituted anilide ring (→ Azo Dyes; Colour Index) have been described. However, these derivatives only became important when the price of 2-hydroxy-3-naphthoic acid arylides fell as a result of the widespread use of Naphtol AS developing dyes.

Naphtol AS derivatives are produced by condensing 2-hydroxy-3-naphthoic acid with appropriately substituted anilines in the presence of phosphorus trichloride in aromatic hydrocarbons (e.g., toluene or xylene). The Naphtol AS derivatives (Red Naphtols) produce orange, red, maroon, or brown shades with diazotized aromatic amines, the red hues being particularly important. A wide range of Naphtol AS pigments is available commercially, some of which are produced in considerable amounts.

The pigments generally have high tinting strength, good resistance to chemicals, and good lightfastness, even in light shades. The somewhat poorer solvent fastness can be improved by incorporating amide groups.

C.I. Pigment Red 112, 12370 [*6535-46-2*] is the most important Naphtol AS pigment and is the only one included among the 20 most important organic pigments:

Because of its brilliant medium-red shade, high lightfastness, and good weather resistance, it is used in paints and printing inks in a wide variety of vehicles. Its unsatisfactory migration fastness results in the pigment not being used in plastics. Production is described in Section 4.1.3.

In some red Naphtol AS pigments, 2-methyl-5-nitroaniline is the diazo component. Exam-

ples are *C.I. Pigment Red 8, 12335* [*6410-30-6*] (**24**); *C.I. Pigment Red 17, 12390* [*6655-84-1*] (**25**); and *C.I. Pigment Red 22, 12315* [*6448-95-9*] (**26**):

24: $R^2 = H$, $R^4 = Cl$
25: $R^2 = CH_3$, $R^4 = H$
26: $R^2 = R^4 = H$

In Europe, Pigment Red 8 is most important, whereas in the United States and Japan, Pigment Red 22 is used on a large scale. All three are used mainly in printing inks.

The color of Pigment Red 17 (**25**) is considerably shifted to the bathochromic side of the spectrum in its isomer *C.I. Pigment Red 12, 12385* [*6410-32-8*]:

Displacement of the nitro group of the diazo component from the 5- to the 4-position changes the shade from a yellowish red to a bluish red (maroon). Pigment Red 12 is used primarily in paints.

In addition to 2,4,5-trichloroaniline, other chlorine-substituted anilines are also used as diazo components. An example is *C.I. Pigment Red 9, 12460* [*6410-38-4*] (**27**):

27

This compound is used mainly to pigment printing inks for letterpress and offset printing.

Pigments with a higher solvent resistance and bleeding fastness are obtained by introducing further carbonamide groups. Such pigments are also suitable for stoving enamels. *C.I. Pigment Orange 38, 12367* [*12236-64-5*] (**28**), for example, is a yellowish-red pigment that can also be used to pigment PVC.

28

C.I. Pigment Red 146, 12485 [*5280-68-2*] (**29**) (Carmine) has a bluish-red shade. Because of its good solvent fastness it is widely used in paints and plastics, as well as special print finishes that can be oversprayed or laminated.

29

C.I. Pigment Red 170, 12475 [*2786-76-7*] (**30**) is a brilliant bluish-red pigment with good lightfastness and weather resistance. It is used mainly in industrial paints.

30

Another modification of the pigment with a greater hiding power and a more yellowish-red shade has even better fastness properties.

Pigment Red 146 (**29**) and Pigment Red 170 (**30**) are used in combination with inorganic red pigments (e.g., molybdate red) to produce particularly clean red shades with a high hiding power that are useful for industrial paints.

C.I. Pigment Red 187, 12486 [*59487-23-9*] contains three amide groups:

This bluish-red pigment is used to color PVC and polyolefins (including polypropylene for spin dyeing) because of its excellent migration fastness and thermal stability.

Naphtol AS pigments are not generally suitable for high-quality, exterior-use paints (automotive finishes). They are employed only in special cases to pigment plastics (e.g., PVC) because their migration fastness (e.g., with respect to overpainting, bleeding, and blooming) is generally unsatisfactory.

Migration-fast azo pigments that do not contain any lake-forming groups can be produced either by incorporating additional carbonamide groups or by substantial enlargement (doubling) of the molecule (see Section 4.8).

Incorporation of additional amide groups in the pigment molecule is particularly effective when these groups are part of a 5- or 6-membered, fused, heterocyclic ring.

Five-membered heterocyclic rings in the coupling component are extremely important technically in benzimidazolone pigments (Section 4.7).

4.7. Benzimidazolone Pigments [3, p. 523], [20]

The benzimidazoline pigments were developed by Hoechst and have been described in the patent literature since 1960 [21]. They contain a cyclic urea group (i.e., benzimidazolone ring) in the coupling component.

In yellow pigments the coupling component is 5-*N*-acetoacetylaminobenzimidazolone:

In red pigments the Naphtol AS derivative is used:

The coupling components are produced by reacting acetoacetic ester or diketene with 5-aminobenzimidazolone (yellow pigments) or by condensing 2-hydroxy-3-naphthoic acid with 5-aminobenzimidazolone in the presence of phosphorus trichloride as in the synthesis of Naphtol AS derivatives described in Section 4.6 (red pigments).

Diazotization of substituted anilines, followed by coupling with the above components, gives monoazo pigments of the Hansa Yellow type in the yellow range and of the Naphtol AS type in the red range.

The crude products are generally in an unsatisfactory crystalline state, which mostly results in pigments with hard particles that are difficult to disperse. The products are therefore usually thermally aftertreated in water, organic solvents, or mixtures of the two (Section 4.1.1).

These pigments can be produced with the same shade spectrum as azo pigments (i.e., ranging from greenish yellow through orange, red, carmine, maroon, and violet to brown). They have excellent solvent, overpainting, and bleeding fastnesses. These properties, as well as lightfastness and weather resistance, are superior to comparable Hansa Yellow and Naphtol AS pigments. Some benzimidazolone pigments are as lightfast and weather resistant as high-quality polycyclic pigments.

Many members of this class are used in high-quality industrial and exterior-use paints (e.g., automotive finishes, special metal-effect paints), plastics, and special printing inks. Some examples follow.

C.I. Pigment Yellow 120, 11783 [*29920-31-8*] is a yellow pigment with high tinting strength and good thermal stability. It is therefore used to particular advantage in plastics:

C.I. Pigment Yellow 151, 13980 [*61036-28-0*] is a pure greenish-yellow pigment that is used particularly in high-quality industrial paints, but also in plastics and lightfast prints:

C.I. Pigment Yellow 154, 11781 [*63661-02-9*] is used particularly for high-quality paints because of its good lightfastness and weather resistance:

C.I. Pigment Orange 36, 11780 [*12236-62-3*] is also well suited to high-quality paints and coating materials (e.g., automotive finishes) and plastics:

Pigments in which 2′-hydroxy-3′-naphthoyl-5-aminobenzimidazolone is used as coupling component include:

C.I. Pigment Red 175, 12519 [*6985-92-8*]

C.I. Pigment Red 176, 12515 [*12225-06-8*]

C.I. Pigment Violet 32, 12517 [*12225-08-0*]

C.I. Pigment Brown 25, 12510 [*6992-11-6*]

4.8. Disazo Condensation Pigments

[3, p. 561]

By use of bifunctional compounds, the molecules of conventional yellow and red monoazo pigments can be "doubled in size".

An attempt to produce such pigments was first made in the red range (Naphtol AS range) by double coupling of diazotized amines with bisnaphthols. However, in most cases, uniform pigments were not obtained. An industrially practicable method of synthesis was first discovered in 1951 by M. Schmid at CIBA, who condensed two monoazo pigment acid chlorides with one diamine. Pigments produced by this method are known as disazo condensation pigments.

4.8.1. Yellow Pigments

Yellow disazo condensation pigments have the two basic structures **31** and **32** shown in Figure 1.

Compounds of general formula **31** are produced by double coupling of diazotized aminobenzoic acids with the bisacetoacetylated coupling component, followed by conversion of the acid to the acid chloride and, finally, condensation with two equivalents of an aromatic amine.

In the synthesis of **32**, two equivalents of the coupling product formed from diazotized aminobenzoic acid and an *N*-acetoacetarylide (monoazo dye carboxylic acid) are converted to

Figure 1. Basic structures of yellow disazo condensation pigments
A denotes the aromatic residue of a diamine. The aromatic rings B – E may include additional substituents (e.g., CH_3, OCH_3, Cl, Br, NO_2, OC_2H_5, $COOCH_3$).

the acid chloride and condensed with an aromatic diamine.

Theoretically, one-stage synthesis of disazo condensation pigments is also conceivable (i.e., in the case of **31** by double coupling of the diazotized aminobenzarylides with the bifunctional coupling component, or in the case of **32** by coupling the bisdiazo component with two equivalents of an *N*-acetoacetarylide). This is, however, impossible because, in both cases, the sparingly soluble monoazo pigment precipitates and is therefore only partially available for further reaction. The same applies to red disazo condensation pigments.

Examples of yellow disazo condensation pigments (mainly type **31**) are shown in Figure 2.

4.8.2. Orange, Red, and Brown Pigments

Orange, red, and brown disazo condensation pigments generally have the structure **33**:

33

where A denotes the aromatic residue of a diamine; rings B may contain further substituents, including those with additional CONH groups. Like the yellow pigments, red pigments are produced by stepwise synthesis (see also Section 4.8.1):

1) Coupling of a diazotized amine with 2-hydroxy-3-naphthoic acid to form the monoazo dye acid
2) Conversion of the acid into the acid chloride with thionyl chloride, phosphorus oxychloride, or phosphorus pentachloride, if necessary in an organic solvent
3) Condensation of two equivalents of the monoazo dye acid chloride with one equivalent of an aromatic diamine in an organic solvent (e.g., 1,2-dichlorobenzene)

Examples of industrially important pigments follow.

4.8.3. Properties

Due to their large molecular size, disazo condensation pigments have extremely good migration and solvent fastness, good thermal stability, high tinting strength (disazo pigments), and in some cases, better lightfastness and weather resistance than analogous monoazo pigments. These properties make them particularly suitable for the plastics and paint sectors.

5. Metal-Complex Pigments

Metal- complex pigments, with the exception of the large group of copper phthalocyanine pigments (→ Phthalocyanines, see also Chap. 7), are only of minor importance. Water-soluble metal complexes are, however, very important in textile dyes (Azo Dyes; → Metal-Complex Dyes, Chap. 5.1.).

One group of industrially important metal-complex pigments consists of 2,2′-dihydroxyazo compounds (**34**), which react with metals (primarily copper, nickel, cobalt, or zinc) to form 1 : 1 metal complexes (**35**) or 1 : 2 metal complexes (**36**).

35a

or

35b

37

34

35

36

Azomethine metal complexes have also achieved a certain importance as pigments; here, the azo group −N=N− is replaced by an azomethine group −N=CH−.

In 1 : 1 azo metal complexes, specific coordination with the metal atom does not occur (**35a** and **35b**). Azomethine metal complexes, however, can only exist in one form (**37**). (see figure on top of this page)

Metalation of 2,2′-dihydroxyazo or azomethine compounds is generally performed with the appropriate metal salt in a variety of solvents.

The absence of solubilizing groups is a prerequisite for the pigment character of metal complexes. Metal- complex formation improves the lightfastness and the solvent, bleeding, and weather resistances of metal-free compounds. However, this is often offset by a dull shade.

5.1. Azo Metal-Complex Pigments

C.I. Pigment Green 10, 12775 [*51931-46-5*] (Nickel Azo Yellow) [3, p. 513] is the only azo metal- complex pigment of any industrial importance.

The yellowish-green pigment was developed by Du Pont in 1941 and came onto the market in 1946. It was long considered to be the azo pigment with the best lightfastness and weather resistance; however, it is only moderately resistant to acid and alkali, and has an inadequate bleeding fastness in stoving enamels. The pigment is used mainly in paints (e.g., in combination with phthalocyanine blue pigments) and, to a lesser extent, in plastics.

Interesting azo metal complexes, including the nickel complex of azobarbituric acid *C.I. Pigment Yellow 150, 12764* [*68511-62-6*] (**38**), have been described as pigments in the patent literature [22].

38

The exact structure of the nickel complex is unknown, though it is assumed to be a 1 : 1 layer complex [23]. The pigment is particularly suitable for paints because of its good lightfastness.

Azobarbituric acid can be obtained from 4-toluenesulfonyl azide and barbituric acid, which react to form diazobarbituric acid. The latter is then coupled with barbituric acid [24].

5.2. Azomethine Metal-Complex Pigments

Azomethine metal-complex pigments have been described by several companies. These predominantly yellow and orange pigments generally have outstanding lightfastness and weather resistance, and may therefore be used to particular advantage in paints subject to extremely stringent requirements [i.e., automotive finishes in single or metallic (aluminum) shades].

For example, the metal (mainly Cu) complexes of 2,2′-dihydroxyazomethines have interesting pigment properties. They are obtained from aromatic 2-hydroxyaldehydes and 2-aminophenols. Examples include *C.I. Pigment Yellow 117, 48043* [*21405-81-2*] (**39**) [25] and *C.I. Pigment Yellow 129, 48042* [*68859-61-0*] (**40**).

39

40

C.I. Pigment Orange 65, 48053 [*20437-10-9*] is obtained from *o*-phenylenediamine and 2-hydroxynaphthaldehyde after complexation with a nickel salt:

5.3. Miscellaneous Metal-Complex Pigments

Another basic structure, which however does not embody typical azomethine metal complexes, is represented by nickel complexes of the anilides of 2,3-dioximinobutyric acid [7], [26]:

Different colors can be produced by varying the substituents R^2, R^4, and R^5:

C.I. Pigment Yellow 153, 48545 [*68859-51-8*]:
$R^2 = R^4 = R^5 = H$
Orange: $R^2 = OCH_3$, $R^4 = R^5 = H$
Red: $R^2 = R^4 = OCH_3$, $R^5 = H$

The pigments have good fastness properties and a high tinting strength [27]. They are produced by nitrosating the appropriately substituted *N*-acetoacetarylide with sodium nitrite in acetic acid, followed by formation of the oxime with a hydroxylamine salt:

The metal complex is formed by reaction with a nickel(II) salt.

Isoindolinone metal-complex pigments (see also Chap. 6) are obtained by condensation of isoindoline with 2-aminobenzimidazole or 2-cyanomethylenebenzimidazole at ca. 130 °C, followed by complex formation with cobalt salts.

Examples include *C.I. Pigment Yellow 177, 48120* [*60109-88-8*] and *C.I. Pigment Yellow 179, 48125* [*63287-28-5*]:

Pigment Yellow 177

Pigment Yellow 179

6. Isoindolinone and Isoindoline Pigments [3, p. 703], [28]

6.1. Azomethine Type: Tetrachloroisoindolinone Pigments

Tetrachloroisoindolinone pigments contain two > C=N groups and must be regarded as a special type of disazomethine pigments. They consist of two tetrachloroisoindolinone rings joined by a diimine bridge:

41

where A denotes an aromatic diamine residue.

The first nonchlorinated isoindolinone pigments were described in 1946 in an ICI patent. In 1952 and 1953, other authors published pigment syntheses based on the condensation of two equivalents of 3-amino-1-isoindolinone with diamines.

None of these "precursors" has the high tinting strength or the remarkable fastness (e.g., to solvents, light, and weathering) of the tetrachloroisoindolinone pigments, which were first described by GEIGY in 1964. Even pale shades of these pigments are extremely lightfast and weather resistant. The reasons for the high fastness are still unknown: it is assumed that intermolecular donor–acceptor complexes are formed between the phenyl or diamine residue and the chlorine-containing moiety of the molecule. The central aromatic ring A must be perpendicular to the two tetrachloroisoindolinone residues for steric reasons. Because of their good fastness properties the pigments are suitable for high-quality paints and plastics. The shade of the pigments is determined by the nature of the diamine residue: a larger conjugated system (diphenyldiamine residue) produces a bathochromic shift compared to a phenylenediamine residue.

The pigments are synthesized primarily by three methods:

1) Condensation of a diamine with two equivalents of a tetrachloroisoindolinone containing two chlorine atoms or methoxy groups as substituents in the 3-position:

2) Condensation of a diamine with two equivalents of a tetrachloroisoindolinone containing an imino group in the 3-position:

3) In a process developed by Dainippon Ink [29], two equivalents of tetrachlorophthalic anhydride are condensed with an aromatic diamine and ammonia in the presence of phosphorus pentachloride to form the bisacyl compound **42**, followed by ring closure with additional phosphorus pentachloride in trichlorobenzene to form the tetrachloroisoindolinone:

42

Examples of tetrachloroisoindolinone pigments include the greenish-yellow compound *C.I. Pigment Yellow 109, 56284* [*12769-01-6*] and the reddish compound *C.I. Pigment Yellow 110, 56280* [*5590-18-1*]. These pigments are used for paints, plastics, and high-quality printed products.

Pigment Yellow 109

Pigment Yellow 110

6.2. Methine Type: Isoindoline Pigments

In methine-type pigments the isoindoline ring is coupled to two methine bridges:

where $R^1 - R^4$ can denote CN, CONH-alkyl, CONH-aryl, CONH-heteroaryl; R^1 and R^2 and/or R^3 and R^4 may also be members of a heterocyclic ring.

An example is *C.I. Pigment Yellow 139, 56298* [*36888-99-0*] (**43**), a barbituric acid derivative of isoindoline [30]:

43

This reddish-yellow pigment has good light- and solvent fastness, and is produced by heating aminoiminoisoindolenine (diiminoisoindoline) with two equivalents of barbituric acid in glacial acetic acid or another solvent.

A red pigment of this type is *C.I. Pigment Red 260, 56259* [*71552-60-8*]; it has the following formula [31]:

C.I. Pigment Orange 66, 48210 [*68808-69-5*] is a yellowish-orange pigment that is used particularly in paints:

7. Phthalocyanine Pigments

Phthalocyanine pigments are the most important group of organic pigments worldwide and are described in detail elsewhere (→ Phthalocyanines).

By following the description given by De Diesbach (1927), copper phthalocyanine was first produced at about the same time by chemists at Scottish Dyes, Ltd. The first blue pigment of this type appeared on the market in 1935, and the first green pigment in 1938. Of historical interest is the fact that this pigment class was the first to be introduced industrially without previously having been used as a dye.

Five crystal modifications of copper phthalocyanine are known, of which the α- and β-types are of practical importance. The ε-modification is also of interest because of its reddish-blue shade. Phthalocyanines are the most important blue and green organic pigments because of their high tinting strength and outstanding stability with respect to light, weather, chemicals, and solvents, as well as their relatively low cost. Other blue and green organic pigments are only economically important for special applications.

Phthalocyanine pigments are suitable for all areas of use, such as paints and coating materials (including the shading of black and white hues), plastics, printing inks, and spin dyeing. The β-modification of phthalocyanine has been adopted as the standard blue (blue-green) shade of the European Scale for letterpress printing.

8. Quinacridone Pigments [3, p. 601], [32]

Quinacridone pigments are polycyclic and consist of five six-membered rings in a linear arrangement. The two peripheral rings are joined to the middle aromatic ring by two 4-pyridone rings:

The two outer aromatic rings may be substituted.

Angular quinacridones were first mentioned in 1896; the linear ring system was described by LIEBERMANN in 1935 [33]. The significance of linear quinacridones as pigments was, however, only recognized in 1955 by W. STRUVE (Du Pont), who discovered a variation of the Liebermann process that enabled pure linear quinacridones to be produced on an industrial scale. He also recognized that unsubstituted quinacridone exists in different modifications, and described a process for their isolation.

In 1958, Du Pont introduced the first quinacridone pigments on the market. These pigments have since undergone significant development, particularly in Western industrialized countries, because they fill a gap in the range of bluish-red and red-violet pigments with outstanding fastness.

8.1. Production

The production of quinacridone pigments consists of synthesis and aftertreatment. If the pigment crystallizes in various forms (polymorphism), aftertreatment can be used to obtain a desired crystal modification (conditioning, finishing). However, crystal quality can also be improved by aftertreatment.

Unsubstituted quinacridones, dimethylquinacridones, dichloroquinacridones, and some mixed crystal phases, in some cases with quinacridonequinone, are available commercially.

8.1.1. Synthesis

Quinacridone [*1047-16-1*]. The process developed in 1955 by Du Pont is still industrially important for the synthesis of quinacridone. The succinosuccinate ester (**44**), which is easily obtained from dimethyl or diethyl succinate, is reacted with two equivalents of an aromatic amine (aniline, *p*- or *m*-toluidine, 4- or 3-chloroaniline) to form the 2,5-diarylamino-3,6-dihydroterephthalic acid diester (**45**). The latter can be converted directly to dihydroquinacridone (**46**) in the same reaction medium at 250 °C (thermal ring closure):

Dihydroquinacridone (**46**) can be oxidized to quinacridone with air or with sodium 3-nitrobenzenesulfonate in aqueous ethanol in the presence of sodium hydroxide. If a low sodium hydroxide concentration is used (ca. 2 % in the solvent mixture), the reaction mixture is oxidized heterogeneously (solid-state oxidation); with ca. 30 % sodium hydroxide in the solvent mixture, oxidation proceeds in homogeneous solution (solution oxidation). Different crystal modifications are formed depending on the nature of the reaction.

Another method is closely related to the synthesis described by LIEBERMANN. Here, the succinosuccinate ester (**44**) is condensed with an arylamine to form the ester **45**. The latter is oxidized to form the 2,5-diarylaminoterephthalic acid diester (**47**), from which the acid (**48**) is obtained by hydrolysis. The acid can be cyclized with polyphosphoric acid or other acid condensation agents to form the quinacridone (acid ring closure).

Another process permits the synthesis of asymmetrically substituted quinacridones, and starts from 2,5-dichloro- or 2,5-dibromoterephthalic acid. The halogen atoms can be replaced successively by arylamine residues (Sandoz). Cyclization is then performed as described above with acid condensation agents to form the quinacridone.

Another synthesis that proceeds via hydroquinone-2,5-dicarboxylic acid has been developed by BASF [32], [34].

Quinacridonequinone (C.I. 73920). A derivative that is of interest particularly for mixed crystal phases is the linear *trans*-quinacridonequinone (**50**). The compound can be prepared by cyclizing 2,5-bis(2′-carboxyanilino)-1,4-benzoquinone (**49**) with concentrated sulfuric acid or polyphosphoric acid at 150 – 200 °C. The starting material is obtained by condensing *p*-benzoquinone with anthranilic acid.

49 **50**

8.1.2. Aftertreatment

Quinacridone pigments can form different crystal modifications. Some of them are very significant industrially because of their outstanding fastness properties. Selective preparation of these modifications by aftertreatment of crude quinacridones is crucial.

Various crystal modifications of dihydroquinacridone may be formed in the synthesis of unsubstituted quinacridone by the Du Pont process, depending on the thermal ring closure method (see Section 8.1.1). The different forms of dihydroquinacridone yield various modifications of quinacridone, depending on the nature of the subsequent oxidation. For example, solid-state oxidation of α-dihydroquinacridone produces crude α-quinacridone, whereas solution oxidation produces crude β-quinacridone.

After synthesis, the crude pigment is usually finely divided by grinding it with salts in the presence of solvents that change or maintain the crystal modification. For example, with xylene the β-phase of the quinacridone pigment is obtained; dimethylformamide produces the γ-phase.

If quinacridone is synthesized by acid ring closure, the crude product occurs in a very finely divided form. The desired crystal modification can be obtained by suitable choice of solvent in subsequent thermal aftertreatment. For example, alkaline pretreatment followed by solvent treatment produces the β-phase of the quinacridone pigment, whereas direct solvent treatment yields the γ-phase.

The β-modification is usually formed by nonpolar solvents, whereas the γ-modification is formed by polar solvents.

8.2. Properties

Quinacridone pigments are insoluble in most organic solvents and all application media, and have high lightfastness and weather resistance as well as good general fastness. These properties are due to the formation of hydrogen bonds between the NH and CO groups of the molecules in the crystal lattice.

In solution, quinacridones have a pale yellow to orange color; the intense red color (with a yellowish-red to violet hue) is thus only formed by interactions in the crystal. Three-dimensional X-ray analyis revealed different crystal structures for the β- and γ-modifications: β-quinacridone forms crystal layers connected by intramolecular hydrogen bonds, the γ-phase has a "criss-cross" structure [35]. Color and properties can be influenced by altering particle size as well as in three ways:

1) Changing the crystal modification
2) Introducing substituents into the ring system
3) Forming mixed crystals of quinacridone with substituted quinacridones or with quinacridonequinone (**50**)

Quinacridone pigments, like the phthalocyanines, are among the organic pigments with the most outstanding fastness properties. They can comply with extremely stringent requirements (e.g., for industrial paints, particularly automotive finishes). They are, however, also used for the weatherfast coloring of plastics, for melt-spin dyeing, and for special printing inks. Their

good thermal stability means that they can also be used to color thermoplastics with a high softening point (e.g., polyolefins).

Examples of Commercial Products.

C.I. Pigment Violet 19, 46500 [*1047-16-1*], β-modification, has a violet shade and high tinting strength that makes it particularly suitable for adjusting red shades in automotive finishes by shading molybdate orange pigments; it can also be used for metallic finishes. Most of its important fastness properties are superior to those of the tetrachlorothioindigo pigments with similar shades (see Chap. 13).

C.I. Pigment Violet 19, 46500, γ-modifications, is another industrially important modification of unsubstituted quinacridone. Depending on particle size, commercial grades range from bluish-red (more transparent) types to yellowish-red (more hiding) types. These grades are used especially in automotive finishes (e.g., to shade inorganic pigments).

C.I. Pigment Red 122, 73915 [*980-26-7*] (2,9-dimethylquinacridone, **51**) is obtained by ring closure of 2,5-bis-(4′-methylanilino)terephthalic acid (or esters) with acid condensation agents. It has a very pure bluish-red shade that lies between that of the β- and γ-modifications of Pigment Violet 19.

51

C.I. Pigment Red 202, 73907 [*68859-50-7*] (2,9-dichloroquinacridone, **52**) is formed from 2,9-dichlorodihydroquinacridone by solid-state oxidation (see Section 8.1.1) or from 2,5-bis-(4′-chloroanilino)terephthalic acid with sulfuric acid or polyphosphoric acid as condensation agent. The bluish-red modification of this pigment is of industrial importance.

52

A yellowish-red dichloroquinacridone consists of a mixture of isomers, mainly 3,10-dichloroquinacridone, with an extremely clean shade.

Quinacridone mixed crystal phase pigments [34] include quinacridone (Pigment Violet 19) and quinacridonequinone (C.I. 73920). Whereas quinacridonequinone (**50**) alone is a pale yellow compound with no outstanding fastness properties (lightfastness), the mixed crystal phase with quinacridone has an interesting gold-orange shade with extremely good general fastness properties. The X-ray powder diffraction diagram shows a spectrum of reflection angles that are completely different from those of the individual pigments. To prepare the mixed crystal phase, a suspension of dihydroquinacridone (see Section 8.1.1) can be reacted with less than the molar amount of an oxidizing agent (e.g., chromate).

C.I. Pigment Red 207, a lightfast, scarlet pigment, consists of mixed crystals of quinacridone, Pigment Violet 19, and 4,11-dichloroquinacridone, C.I. 73906.

9. Perinone Pigments

The perinone pigments are synthesized from 1,4,5,8-naphthalenetetracarboxylic acid (**53**) or its monoanhydride (**53a**):

53 **53a**

The pigments are produced by reacting the anhydride with aromatic 1,2-diamines.

Naphthalenetetracarboxylic acid (**53**) is obtained by reacting acenaphthene (**54**) with malonodinitrile and aluminum chloride according to the Friedel–Crafts reaction. The condensation product (**55**) is then oxidized to di-

chloroacenaphthindandione (**56**) with sodium chlorate and hydrochloric acid. Finally, **56** is oxidized with sodium hypochlorite and potassium permanganate:

In another process, pyrene is halogenated to form the symmetric 1,3,6,8-tetrahalogen derivative, which is then hydrolyzed with sulfuric acid and oxidized to a diperinaphthindandione. The latter is finally oxidized in an alkaline medium to produce the tetrasodium salt of naphthalenetetracarboxylic acid [11].

A mixture of the two perinone isomers *Pigment Red 194* [*4216-02-8*] (**57**) and *Pigment Orange 43* [*4424-06-0*] (**58**) is obtained by condensing two equivalents of 1,2-diaminobenzene with one equivalent of naphthalenetetracarboxylic acid (e.g., in boiling glacial acetic acid).

Originally only the isomer mixture was commercially available as a yellowish-red vat dye (*C.I. Vat Red 14, 71110*). The two isomers were subsequently separated by fractional precipitation with sulfuric acid or by heating in ethanol and potassium hydroxide, the *trans* isomer precipitating as the sparingly soluble potassium addition compound. The *cis* isomer Pigment Red 194 (**57**) has a dull red shade, whereas the *trans* isomer Pigment Orange 43 (**58**) has a pure orange shade.

Only when the importance of organic pigments increased was it recognized that some of the sparingly soluble vat dyes, including the perinones, could be used as pigments. Both isomers, but especially the orange *trans* compound, are now important organic pigments; they are marketed by several companies.

C.I. Pigment Orange 43, 71105 [*4424-06-0*] (**58**) is a brilliant orange pigment with a very high tinting strength, very good lightfastness, and weather resistance; good solvent and migration fastness; and outstanding thermal stability. It is particularly suitable for pigmenting plastics [e.g., PVC, polyolefins, and ABS (acrylonitrile – butadiene – styrene)], as well as for spin dyeing (e.g., of awnings and tents). In paints the pigment is used for powerful brightening effects and shading. Copper shades can be obtained by combining it with aluminum pigments.

C.I. Pigment Red 194, 71100 [*4216-02-8*] (**57**) is a red pigment with a high tinting strength but somewhat dull shade. Its lightfastness and weather resistance are outstanding, particularly in stoving enamels.

10. Perylene Pigments

The perylene pigments are based on 3,4,9,10-perylenetetracarboxylic acid diimides (**59**):

Like perinones (Chap. 9), the perylenetetracarboxylic acid diimides have long been known as vat dyes but have only recently become important pigments.

Production. Perylene pigments are generally prepared by heating perylenetetracarboxylic anhydride with primary aromatic or aliphatic amines in high-boiling solvents.

3,4,9,10-Perylenetetracarboxylic acid (**61**) is obtained by reacting 1,8-naphthalic acid imide

(**60**) with molten potassium hydroxide, followed by atmospheric oxidation to produce perylenetetracarboxylic acid diimide (**59**, R=H). The diimide is then hydrolyzed to give **61**. 1,8-Naphthalic acid imide (**60**) is synthesized by oxidizing acenaphthene (**54**) to 1,8-naphthalenedicarboxylic anhydride, which is then reacted with ammonia.

N,N′-dimethylperylimide is obtained from perylenetetracarboxylic acid diimide (**59**, R = H) by methylation.

Properties and Important Products. Perylene pigments have very good lightfastness, good to very good migration fastness, and high thermal stability. They are therefore used mainly to pigment plastics, but also as high-quality stoving enamels (e.g., for automobiles).

Commercial products are listed in Table 2. The most important of these are Pigment Red 149, 178, 179, and 190.

11. Anthraquinone Pigments

The term anthraquinone pigments denotes pigments that are anthraquinone derivatives or have a similar structure to anthraquinone (including higher condensed ring systems). With the exception of hydroxyanthraquinonesulfonic acid (see Section 11.1) and the anthraquinone azo pigments (see Section 11.2), all other compounds discussed in this chapter have long been used as vat dyes for dyeing textile fibers. Initial attempts to use these vat dyes as pigments generally produced dull shades and moderate tinting strengths. Vat dyes could only be used as pigments when methods became available for obtaining the required reproducible properties (e.g., higher chemical purity, optimum particle size and distribution, and appropriate crystal modifications).

The vat dyes were successfully converted into readily dispersible pigments by various aftertreatments including

1) Reduction to the leuco dye, removal of impurities, and reoxidation
2) Dissolution of the raw material (for example in sulfuric acid), precipitation in water or organic solvents, possibly with the addition of surfactants under carefully selected conditions
3) Thermal aftertreatment in water or organic solvents
4) Use of a wide range of dispersion and grinding processes (e.g., bead or ball mill grinding, comminution in the presence of salts or solvents)

Relatively few of the large number of vat dyes satisfy pigment requirements. Of these, only a small number have fastness standards approaching those of the phthalocyanine pigments. See also→ Anthraquinone Dyes and Intermediates, Chap. 3.1.4.

11.1. Hydroxyanthraquinone Pigments

Many derivatives of hydroxyanthraquinones and their sulfonic acids used to be commercially available as pigments, predominantly in the form of aluminum lakes. The number of these industrially important products has, however, fallen sharply. An example is *C.I. Pigment Violet 5:1, 58055:1* [*1328-04-7*]:

The commercially important form of this product is the 2:1 aluminum complex.

Table 2. Commercially available perylene pigments [36]

R (in formula **59**)	C.I. name, formula no.	CAS registry number	Shade
H	C.I. Pigment Violet 29, 71129	[*12236-71-4*]	red to maroon
H_3C	C.I. Pigment Red 179, 71130	[*5521-31-3*]	red to maroon
	C.I. Pigment Red 190, 71140	[*6424-77-7*]	bluish red
	C.I. Pigment Red 123, 71145	[*24108-89-2*]	scarlet to red
	C.I. Pigment Red 149, 71137	[*4948-15-6*]	red
	C.I. Pigment Red 178, 71155	[*3049-71-6*]	red
N – R = O	C.I. Pigment Red 224, 71127	[*128-69-8*]	bluish red

The hydroxyanthraquinones 1,2-dihydroxyanthraquinone (alizarine), 1,4-dihydroxyanthraquinone (quinizarin), and 1,2,4-trihydroxyanthraquinone (purpurin), some of which are metal-complex pigments. Alizarine, for example, was sold as the aluminum calcium salt of 1,2-dihydroxyanthraquinone [37].

11.2. Aminoanthraquinone Pigments

For the preparation of aminoanthraquinones, see → Anthraquinone Dyes and Intermediates, Chap. 2.5.

Several commercially available compounds were synthesized by acylation or benzoylation of monoamino- or diaminoanthraquinones or their hydroxy derivatives. Very few pigments in this range are still industrially important.

Anthraquinone azo pigments and anthraquinone pyrimidines are condensation products of aminoanthraquinone and are also discussed here.

Acylaminoanthraquinones. The reddish-yellow *C.I. Pigment Yellow 147, 60645* [*76168-75-7*] is obtained by condensation ("acylation") of 1-aminoanthraquinone with 2,4-dichloro-6-phenyl-1,3,5-triazine.

Aminoanthraquinones with Free Amino Groups. *C.I. Pigment Red 177, 65300* [*4051-63-2*] is used in high-quality paints, particularly for automobiles.

Anthraquinone Azo Pigments. Red to yellow pigments with, in some cases, extremely good general fastness are obtained by diazotization, especially of 1-aminoanthraquinone (→ Anthraquinone Dyes and Intermediates, Chap. 2.5.3.), followed by coupling with various components. Use of coupling components containing additional amide groups improves the migration fastness of the resulting

62

pigments. Red pigments (**62**) are obtained by coupling with Naphtol AS derivatives [38] (see above).

If barbituric acid is used as the coupling component, a yellow pigment (**63**) is obtained [39]:

63

Orange or red pigments [40] with good fastness properties are synthesized by coupling diazotized 1-aminoanthraquinone with pyrazoloquinazolines of the formula:

An example of such a pigment is *C.I. Pigment Red 251, 12925* [*71552-60-8*].

11.3. Heterocyclic Anthraquinone Pigments

11.3.1. Anthrapyrimidine Pigments

The anthrapyrimidine pigments are based on 1,9-anthrapyrimidine (→ Anthraquinone Dyes and Intermediates, Chap. 2.12.3.), which can be obtained from 1-aminoanthraquinone:

1,9-Anthrapyrimidine

C.I. Pigment Yellow 108, 68420 [*4216-01-7*], for example, is a greenish-yellow pigment with very good lightfastness and weather resistance. It is obtained by condensing 1-aminoanthraquinone with 1,9-anthrapyrimidine-2-carboxylic acid chloride. The pigment has long been known as a vat dye.

11.3.2. Indanthrone and Flavanthrone

Indanthrone (→ Anthraquinone Dyes and Intermediates). *Indanthrone, C.I. Pigment Blue 60, 69800* [*81-77-6*] was discovered in 1901 by R. Bohn and is one of the oldest vat dyes.

"Indanthren", the original compound name, was employed as a generic term for very high-quality

vat dyes. Subsequently, the compound was also used as a pigment.

Indanthrone is produced on an industrial scale mainly by treating 2-aminoanthraquinone in an alkali melt. Typically, the compound is heated to 210 – 225 °C in a mixture of potassium hydroxide and sodium hydroxide in the presence of sodium nitrate or potassium chlorate and potassium acetate or formate.

The pigment exists in four crystal modifications. The reddish-blue α-phase is of special interest; it has good thermal stability and very good light- and solvent fastnesses, approaching those of the phthalocyanines.

Because of its high cost, indanthrone is used mainly for high-quality paints and plastics, especially polyolefins. Its importance is limited, however, due to the availability of inexpensive phthalocyanine pigments with excellent fastness properties (→ Phthalocyanines).

Flavanthrone (→ Anthraquinone Dyes and Intermediates, Chap. 2.12.7.). *Flavanthrone yellow, C.I. Pigment Yellow 24, 70600* [*475-71-8*] (**64**) was first described in 1901 by R. Bohn.

64

It attracted interest as a pigment when the demand for paints with higher lightfastness and weather resistance increased.

Flavanthrone is synthesized by reacting 1-chloro-2-aminoanthraquinone with phthalic anhydride to give 1-chloro-2-phthaloylaminoanthraquinone. The latter is cyclized to flavanthrone by heating with copper powder in trichlorobenzene at 180 – 200 °C, followed by treatment with excess sodium hydroxide.

The pigment can also be prepared in a one-stage process by heating 1-chloro-2-aminoanthraquinone with copper in a strongly polar aromatic solvent [41].

Various methods are available for purifying the crude pigment, for example:

1) Dissolution in concentrated sulfuric acid followed by hydrolysis
2) Conversion to the leuco form and reoxidation
3) Extraction with dipolar aprotic solvents

The pigment has a somewhat dull, reddish-yellow color, high tinting strength, and very good lightfastness and weather resistance, even in light shades.

11.4. Polycarbocyclic Anthraquinone Pigments

This section deals with polycyclic systems that do not contain hetero atoms (nitrogen). Very few systems are important as pigments.

11.4.1. Pyranthrone Pigments

The pyranthrone structure is related to that of flavanthrone (**64**), the only difference being that the nitrogen atoms of the latter are replaced by carbon atoms. Pyranthrone (pyranthronequinone, **65**) is classified as *C.I. Pigment Orange 40, 59700* [*128-70-1*]:

65

Pyranthrone is prepared from 1-chloro-2-methylanthraquinone (**66**), which is reacted with copper powder in boiling 1,2-dichlorobenzene to give 2,2′-dimethyl-1,1′-dianthraquinonyl (**67**). The latter is cyclized to pyranthrone by boiling for several hours with 50 % potassium hydroxide solution in isobutanol:

Unsubstituted pyranthrone and halogenated pyranthrone derivatives have yellowish-red to red hues with a high tinting strength. Lightfastness and weather resistance are improved by halogenation; tribromopyranthrone, for example, has substantially greater fastness than dibromopyranthrone. The halogenated pyranthrone pigments are mainly used in high-quality paints and coating materials, and also in combination with inorganic or aluminum pigments, especially for automotive finishes.

Halogenation is carried out with chlorine or bromine, preferably in chlorosulfonic acid in the presence of sulfur, iodine, or antimony as catalyst. The chlorine or bromine atoms are introduced in various positions of the pyranthrone ring. Pyranthrones with two to four halogen atoms per molecule can be obtained, depending on the quantity of halogen used [42], [43].

Cyclization of 3,3′-dichloro-2,2′-dimethyl-1,1′-dianthraquinonyl in polar organic solvents at 110 – 150 °C in the presence of alkali acetates yields 6,14-dichloropyranthrone [43]. Bromination of the latter yields bromodichloropyranthrones containing ca. 0.5 – 2.2 bromine atoms per molecule, depending on the quantity of bromine and the reaction conditions. Different shades are produced according to the degree of bromination [44].

Commercially available pigments include 2,10-dichloropyranthrone (*C.I. Pigment Orange 51* [*73309-48-5*]), dibromo-4,6-dichloropyranthrone (*C.I. Pigment Red 226* [*63589-04-8*], $m = 2$, $n = 2$); and tribromopyranthrone (*C.I. Pigment Red 216, 59710* [*1324-33-0*], $m = 0$, $n = 3$).

11.4.2. Anthanthrone Pigments

Anthanthrone (**68**) has the following structure:

Only halogenated anthanthrones are used as pigments. Of particular interest is the yellowish-red (scarlet) pigment 4,10-dibromoanthanthrone, *C.I. Pigment Red 168, 59300* [*4378-61-4*]. This compound has a high tinting strength with extremely good lightfastness and weather resistance. It is mainly used to pigment high-quality industrial paints, but also to a lesser extent in the plastics sector.

Anthanthrone is synthesized from naphthostyryl (**69**), which is hydrolyzed to give 1-aminonaphthalene-8- carboxylic acid (**70**). The latter is diazotized and boiled in the presence of copper powder to yield 1,1′-dinaphthyl-8,8′-carboxylic acid (**71**), which is finally cyclized to anthanthrone (**68**) with sulfuric acid. Dibromoanthanthrone can be obtained directly by bromination of anthanthrone in the presence of iodine.

12. Diketopyrrolopyrrole (DPP) Pigments

A new type of heterocylic pigments based on a symmetrical chromophore, namely, the 1,4-diketopyrrolo[3,4-*c*]pyrrole system (**72**)

72

was discovered in the early 1980s and systematically developed into a group of red pigments (DPP pigments) with good fastness properties [45], [46].

The DPP pigments are synthesized by reacting succinate esters with benzonitriles in methanol in the presence of sodium methoxide:

The particle size and associated properties can be controlled either by solvent aftertreatment or by synthesis conditions. A second benzonitrile derivative can be added during condensation; this mixed synthesis yields pigment types that are more transparent and have a higher tinting strength.

The pigments are extremely lightfast and weather resistant, with a good thermal stability and resistance to bleeding and chemicals. *C.I. Pigment Red 254* is commercially available.

13. Thioindigo Pigments

See also → Indigo and Indigo Colorants, Chap. 13..

Indigo was important at one time as a pigment for coloring rubber but is now seldom used for this purpose. Some thioindigo derivatives became important organic pigments in the 1950s. Thioindigo itself was of some importance as a vat dye for a brief period.

Thioindigo derivatives substituted in the aromatic ring with halogen (in particular chlorine) or methyl groups were first described about 80 years ago and were used up to the 1950s, mainly as vat dyes. Thioindigo derivatives became important as red and maroon pigments when suitable aftertreatment of the crude products had been developed.

Of the few thioindigo pigments still on the market, only the maroon *C.I. Pigment Red 88*, *73312* [*14295-43-3*] (4,7,4′,7′-tetrachlorothioindigo, **76**) is of any importance:

76

This compound has the best fastness properties of all known thioindigo pigments; it has a high lightfastness and weather resistance, even in reduced shades, and a very good migration fastness. The pigment is used in industrial paints, for example, in automotive finishes where it is often combined with inorganic red pigments (molybdate red, iron oxide), and in plastics.

C.I. Pigment Red 88 is obtained by reacting 2,5-dichlorothiophenol (**73**) with chloroacetic acid to form 2,5-dichlorophenylmercaptoacetic acid (**74**). The latter reacts with chlorosulfonic acid with ring closure to form thioindoxyl (**75**), which can be oxidized in an alkaline medium to form 4,7,4′,7′-tetrachlorothioindigo (**76**):

Various ring closure modifications have been described. For example, instead of (substituted) phenylmercaptoacetic acid, its 2- carboxy or 2-amino derivative can be cyclized to thioindoxyl. In the first case, cyclization is carried out in an alkali melt. In the second, cyclization is achieved by diazotization, Sandmeyer reaction with sodium cyanide/copper(I) cyanide, alkaline hydrolysis, and treatment with acid.

C.I. Pigment Red 181, 73360 [*2379-74-0*], 4,4′-dimethyl-6,6′-dichlorothioindigo, is of limited importance for coloring special plastics and cosmetics.

14. Dioxazine Pigments

See also → Azine Dyes, Chap. 5.2.

The parent compound of the dioxazine series is 9,10-dichlorotriphenedioxazine, which itself has no importance as a pigment:

Derivatives with substituents in the two peripheral aromatic rings are of considerable technical interest.

To prepare dioxazine derivatives, chloranil (**77**) is first reacted with aromatic amines in the presence of acid-binding agents (e.g., sodium acetate) to form the 2,5-diarylamino-3,6-dichlorobenzoquinone (e.g., **78**). The corresponding dichlorodiphenedioxazine is obtained by oxidative cyclization of the latter in a high-boiling solvent in the presence of a catalyst (e.g., aluminum chloride or benzenesulfochloride) that lowers the cyclization temperature.

Ring closure is facilitated if 2-alkoxyanilines are used instead of anilines. The oxazine ring is then formed with the elimination of alcohol.

One compound of the dioxazine series has become especially important as a pigment, namely, *C.I. Pigment Violet 23, 51319* [*6358-30-1*] (**79**). The compound was first described as a pigment in 1952 by Hoechst [47]; it was originally used in the sulfonated form as a lightfast, substantive dye. Procedures such as precipitation with chloroacetic acid, phosphoric acid, or *p*-toluenesulfonic acid; salt grinding; or kneading in the presence of an organic solvent were necessary to obtain the required pigment properties.

Three-dimensional X-ray analysis revealed an angular structure (**79**). The pigment exists in two crystal modifications [35].

Pigment Violet 23 has a blue to reddish-violet color and a high tinting strength. It is extremely lightfast and resistant to weathering, and is used in nearly all media, especially to shade the color of phthalocyanine blue pigments.

The pigment is synthesized according to the reaction pathway described above:

Condensation of chloranil with 3-amino-*N*-ethylcarbazole in 1,2-dichlorobenzene in the presence of sodium acetate at 55 – 70 °C yields the dichlorotriphenedioxazine derivative (**78**). The latter is then cyclized at 175 – 180 °C in a Friedel – Crafts reaction in the presence of benzenesulfochloride.

Other dioxazine pigments that are produced industrially on a limited scale contain acetyl or benzoylamino groups in the 2,6-positions and ethoxy groups in the 3,7-positions. The acylamino groups may also replace the chlorine atoms in the 9,10-positions, they are especially important for improving migration fastness.

An example of a dioxazine pigment is *C.I. Pigment Violet 37, 51345* [*57971-98-9*], which is prepared by Friedel – Crafts condensation of 2,5-dichloro-3,6-bisacetylamino-1,4-benzoquinone with 1,4-diethoxy-2-amino-5-benzoylaminobenzene in alcohol in the presence of sodium acetate:

Subsequent ring closure occurs without oxidation by the elimination of alcohol.

15. Triphenylmethane Pigments

Two groups of triphenylmethane (triarylcarbonium) compounds are important as pigments. They are both salts of basic dyes: (1) inner salts of triphenylmethanesulfonic acids and (2) complex salts with inorganic heteropoly acids. Triarylmethane dyes are discussed in detail elsewhere (→ Triarylmethane and Diarylmethane Dyes). Only the two types most important as pigments are briefly discussed here. All interesting triphenylmethane pigments are blue, violet, or green. They are only moderately fast with respect to alkali, but have good fastness with respect to water, oil, acid, and hydrocarbons. Because of their high tinting strength and brilliance they are used for printing, mainly for shading black printing inks, especially sheet and roller offset inks.

15.1. Free Sulfonic Acids ("Alkali Blue" Types)

In contrast to the water-soluble sodium salts of the triphenylmethanesulfonic acids used for dyeing wool, the free sulfonic acids of 4,4′,4″-trisaminophenylmethane and of phenylated "pararosaniline" are generally insoluble in water. The reddish diphenyl derivatives (**80**) and the greenish triphenyl derivatives (**81**) are important pigments. Reddish-blue pigments (**82**) are also used.

R, R¹, R² = H, C_6H_5, C_6H_5 **80**
= C_6H_5, C_6H_5, C_6H_5 **81**
= H, H, C_6H_5, **82**

The compounds are prepared from aniline and *p*-toluidine by acid-catalyzed phenylation with arylamines followed by sulfonation. Alternatively, 4-chlorobenzotrichloride is reacted with chlorobenzene in a Friedel – Crafts reaction to give 4,4′,4″-trichlorotriphenylmethyl chloride. The chlorine substituents of the latter are then replaced by arylamines, and the product is sulfonated [48]. The green shade increases with the number of phenyl groups in the molecule. One sulfonic acid group per molecule is the optimum number; at higher degrees of sulfonation tinting strength decreases and oilfastness deteriorates appreciably.

15.2. Dye Salts with Complex Anions

The triphenylmethane dyes for pigment formation were originally precipitated with tannin and potassium antimonyl tartrate on inorganic substrates (e.g., hydrated alumina, $CaSO_4$, or $BaSO_4$). These pigments had a poor lightfastness. To improve lightfastness and obtain satisfactory brilliance and tinting strength, complex salts were formed with inorganic het-

eropoly acids: phosphotungstic acid, and especially phosphomolybdic and phosphotungstomolybdic acids.

Two types of triphenylmethane dyes are still important for complex formation with the above-mentioned acids which are deprotonated to form anions (A^-), namely, **83**, which produces violet shades, and **84**, which produces blue shades.

83

84

The nitrogen atoms carry either alkyl (e.g., methyl or ethyl) groups, aryl groups, or hydrogen and alkyl or aryl groups.

Xanthene derivatives (rhodamines) are derived from the triphenylmethanes and are also important pigments:

R = H, CH_3, C_2H_5

16. Quinophthalone Pigments [49], [50]

See also → Methine Dyes and Pigments.

Quinophthalone pigments are obtained by fusing quinaldine with phthalic anhydride:

The structure of the enol form and the hydrogen bond were determined by spectroscopy [50].

Quinophthalones containing sulfonyl or carboxyl substituents are important anionic dyes. Quinophthalones with side chains containing basic quaternary amine groups are important as cationic dyes and especially as disperse dyes.

Lightfastness is considerably improved by introducing a hydroxyl group into the 3-position of the quinophthalone molecule (→ Methine Dyes and Pigments).

Attempts have been undertaken to make quinophthalones more solvent- and migration-fast by increasing the size of the quinophthalone molecule through introduction of appropriate substituents, condensation of quinaldines with pyromellitic dianhydride, or "dimerization" of the molecule via a diamide bridge, thus forming quinophthalone pigments. Suitable substituents include acylamino groups and, especially, chlorine or bromine atoms. Introduction of halogen atoms into the phthaloyl residue increases lightfastness, whereas halogen substitution in the phenyl moiety of the quinoline ring decreases lightfastness.

Quinophthalone pigments have yellow to red shades and are used for the bulk dyeing of plastics (e.g., PVC or polyolefins) and rubber, as well as for pigmenting coating materials and printing inks.

Examples. *C.I. Pigment Yellow 138, 56300* [*56731-19-2*], a clear greenish-yellow pigment, is obtained by reacting 8-aminoquinaldine with two equivalents of tetrachlorophthalic anhydride [51]:

A red bisquinophthalone pigment is obtained from pyromellitic anhydride and two equivalents of 3-hydroxyquinaldine-4- carboxylic acid [52] (see above).

17. Fluorescent Pigments [53]

Fluorescent daylight pigments not only reflect light, but also emit a substantial proportion of the light they absorb (→ Fluorescent Dyes, Chap. 12. The wavelength of the emitted light is longer than that of the absorbed light. The term light in this context denotes electromagnetic radiation with a wavelength of ca. 300 – 700 nm (longer-wave UV and visible regions). The color of a fluorescing sample thus consists of a combination of reflected light (intrinsic color) and emitted light. Fluorescent pigments are therefore much more brilliant than normal pigments and have a much higher luminosity.

For fluorescence to occur in organic dyes (i.e., the release of a proportion of the absorbed energy as light), the following conditions must be satisfied:

1) Existence of a planar, delocalized π-electron system that requires only a small energy input to convert it to an excited state.
2) A molecular conformation with maximum rigidity to prevent vibrations that would otherwise lead to radiationless deactivation without emission of light.
3) Most industrially important substances only show fluorescence in the dissolved state. Therefore, the dyes must form dilute solutions because fluorescence is extinguished at high concentrations ($\geq$ ca. 10 %).

Colorants that are not dissolved in the application medium (i.e., pigments) cannot therefore generally be used in the pure state as fluorescing systems. In the mid-1940s, however, Switzer in the United States prepared solid solutions of fluorescent dyes in urea – formaldehyde resins [54] that were suitable as fluorescent pigments.

Of the numerous known fluorescing systems, only a few are used for the industrial production of fluorescent pigments. In the yellow range these include derivatives of 4-aminonaphthalic arylimide, benzoxanthene, benzothioxanthene, coumarin, and naphthaldazine. Rhodamines in particular are suitable for red fluorescent pigments. For more detailed descriptions of these compounds, see → Fluorescent Dyes, → Optical Brighteners.

4-Aminonaphthalic Arylimide Derivatives. An example is *C.I. Solvent Yellow 44, 56200* [*2478-20-8*]. Nitration and oxidation of acenaphthene yields 4-nitronaphthalic anhydride which is reduced and converted to Solvent Yellow 44 by heating with *m*-xylidine.

Benzoxanthene (85, A = O) and benzothioxanthene (85, A = S) derivatives are synthesized, for example, by ring closure of the diazonium salts of 4-(2′-aminophenoxy)naphthalic anhydride or of the corresponding imides in the presence of copper salts at 60 – 100 °C [55].

85

Coumarin Derivatives (→ Fluorescent Dyes, Chap. 3.). The fluorescent dye **86** is prepared by reacting 2- cyanomethylbenzimidazole with 4-diethylamino-2-hydroxybenzaldehyde in ethanol in the presence of piperidine, followed by boiling with 2 % hydrochloric acid [56].

86

Naphthaldazine Derivatives. *C.I. Pigment Yellow 101, 48052* [*2387-03-3*] (**87**) is synthesized from 2-hydroxy-1-naphthaldehyde and hydrazine. It is the only known fluorescent pigment that can be used directly without being embedded in resin.

87

Rhodamines. *C.I. Basic Violet 10, 45170* [*81-88-9*] (Rhodamine B, **88**) is prepared by condensing phthalic anhydride with 1,3-diethylaminophenol at 180 °C in the presence of zinc (II) chloride.

88

Production. Embedding fluorescent dyes in resins produces brittle, strongly fluorescent substances that can be comminuted by grinding but still have a relatively large particle-size distribution (ca. 1 – 30 µm). Fluorescent dyes are now generally embedded in clear, colorless matrix resins that are synthesized by polycondensation of aminotriazines (e.g., benzoguanamine, melamine, or urea) with aromatic sulfonamides and formaldehyde [57] (→ Amino Resins). Urethane resins have also been described, which are obtained by polyaddition of aliphatic diisocyanates with amides and amines [58]. Fluorescent pigments have a much better solvent resistance and lightfastness than fluorescent dyes used in solution.

General Synthesis. The aromatic sulfonamide is heated in a stirred vessel until it melts. Formaldehyde is then slowly added, and a clear, colorless resin is formed. The amine (e.g., benzoguanamine, melamine, urea) is simultaneously added for the cocondensation. The fluorescent dye is then dissolved in the molten resin. With yellow shades the dye concentration may reach ca. 10 %; with orange and red shades, only ca. 2 %. At 150 – 175 °C the hot liquid is poured onto metal sheets and cooled. The clear, brittle resin is comminuted to give an average particle size of 5 – 6 µm.

Uses. Daylight fluorescent pigments are used to color plastics, mainly nonpolar paint binder systems, and printing inks, as well as for textile printing. The pigments are transparent and therefore mainly applied to white substrates. To increase the range of shades, up to three fluorescent pigments (generally premixed as dyes) are often used. Important areas of use include the marking of warning and safety equipment and appliances (e.g., traffic signs; rescue, police, and fire department vehicles). The coloring of plastics and the printing of fluorescent pigments on paper, cardboard, or textiles are very important in the advertising sector.

18. Environmental Aspects

Organic pigments have an extremely low toxicological and ecological risk potential due to their physicochemical properties, particularly their extremely low solubility in water and application media [59]. As with all chemicals, human safety, removal of contamination from emissions and effluents, and proper disposal of waste are of paramount importance in the production and use of pigments.

18.1. Toxicology

Instructions on safe handling published in safety data sheets are based on the results of toxicological and ecological tests.

Testing of hundreds of organic pigments showed that they have extremely high oral LD_{50} values. Very few cause irritation of the skin or mucous membranes.

Numerous pigments have been screened for mutagenic effects in the Ames test [60]. This test was positive in only a few cases involving very small molecules that were slightly soluble in solvents (e.g., dimethyl sulfoxide) used in the Ames test.

To screen for carcinogenic potential, long-term animal feeding tests have to be performed (generally on rats and mice). No studies are known in which a significant carcinogenic potential has been detected for organic pigments. Animal experiments on dichlorobenzidine pigments, for example, showed that the compound was not reductively cleaved to the carcinogenic compound 3,3′-dichlorobenzidine. Furthermore, none of the epidemiological investigations revealed any toxic effects in humans [36]. Long-term feeding tests on Pigment Yellow 12, 13, 16, and 86 did not reveal a carcinogenic effect. The pigments did not exhibit any bioavailability (i.e., were not metabolized) [61].

18.2. Ecology

Organic pigments may be classified as inert dusts because of their sparing solubility in water and the solvents normally employed in their application media. The MAK value specified for fine dusts is 6 mg/m^3. Air, particularly at the workplace, must be kept substantially free from chemicals (pigments) by appropriate removal and separation procedures (filtration, adsorption). Possible exposure to pigment dusts must be prevented by protection equipment (respirators). Contamination of open water with organic pigments can also be avoided by filtration, sedimentation, adsorption, or possibly biological treatment of the effluent. Toxic effects on fish stocks are extremely unlikely because of the sparing solubility of organic pigments, and none have been described.

Organic pigments are not biologically degradable under aerobic conditions but probably decompose slowly under anaerobic conditions.

18.3. Impurities

Pigment impurities (e.g., traces of aromatic amines, heavy metals, or polychlorinated biphenyls, PCBs) may affect the results of toxicological investigations.

Only traces of the aromatic amines used for the synthesis of azo pigments should be present in the pigments. Limiting values for these amines have been laid down for certain areas of application; for example, a limit of 500 ppm has been specified for pigments in food packaging materials.

Traces of heavy metals in organic pigments are generally considerably below official limiting values. Appropriate limits of heavy metals in organic pigments must be obeyed in consumer goods, cosmetics, and toys [62].

In some countries (e.g., in the EC and the United States), strict regulations have been placed on PCBs because of their persistence in the environment. Permissible concentrations in the EC are 50 ppm, and in the United States 25 ppm.

Because of the insolubility and migration fastness of most organic pigments, no particular problems arise in handling and application. Regular tests should be carried out on colored materials and the pigments themselves to protect consumers and ensure that traces of pigments do not migrate from the printed or colored packaging (e.g., into food), and to confirm that the stringent purity requirements and other legal regulations are being observed [63]. Safety standards include EN 71.3, Safety of Toys (1988) for the EC and ASTM F963-86, Standard Consumer Safety Specifications on Toy Safety for the United States.

1. Introduction

Plant growth regulators, also known as bioregulators, are natural or synthetic substances that act in small amounts to influence developmental, metabolic, and growth processes in plants without having lethal effects. In agriculture and horticulture, they are employed to obtain specific advantages, which include increased yields, modification of growth forms, improved quality, modification of plant constituents, and facilitation of harvesting. In the classification of these substances, it is impossible to avoid a certain degree of overlap with the herbicides (→ Weed Control) because higher doses of some agents can also cause damage to the plant. In a broader sense, substances such as defoliants and desiccants are also classified as growth regulators or bioregulators.

Phytohormones. Plants synthesize a system of plant hormones (phytohormones) that regulate metabolic processes. The signal effects of this system on metabolic processes are comparable to those of animal hormone systems (→ Hormones, Chap. 1.1.1.), but differ as regards organ specificity. Animal hormones are synthesized at specific sites and produce an effect in a particular target organ, whereas phytohormones are formed at many sites and act on many different plant organs (multilocal); they therefore have a wide spectrum of activity. Phytohormones interact with one another, producing antagonistic, additive, or synergistic effects.

Five groups of substances are known to be involved in the transmission of external and internal signals from one part of the plant to another:

1) Auxins
2) Gibberellins
3) Cytokinins
4) Abscisic acid
5) Ethylene

Depending on the stage of plant development, varying amounts of hormones are formed in the plant organs in response to environmental stimuli. The stimulatory or inhibitory effect of phytohormones enables the plant to continually regulate vital processes, e.g., growth, differentiation, flowering, maturation, and the shedding (abscission) of leaves. It is often not the type but the concentration of the phytohormone that determines whether a given developmental process is stimulated or inhibited. Obviously, there is a chance that active substances can be used to specifically influence these complicated events, especially in cultivated plants.

History. Scientific findings in the field of plant physiology not only give insight into the molecular basis of plant development, but also provide technical applications that are becoming increasingly important for the cultivation of plants. The use of plant growth regulators in agriculture and horticulture began in the 1930s. They include both natural phytohormones, such as auxin (3-indolylacetic acid) and gibberellic acid (GA_3), as well as synthetic substances, such

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a20_415

as daminozide, chlormequat, and ethephon. Examples of these substances and their applications are listed in chronological order in Table 1. Some are of considerable economic importance (e.g., auxin-type substances, chlormequat), whereas others are no longer in use (e.g., ethylene, acetylene).

Table 1. Plant growth regulators

Year of introduction	Agent (trade name)	Application
1932	ethylene, acetylene	induction of flowering in pineapples
1936	auxin	production of seedless fruit
1943	1-naphthylacetic acid	thinning out of apples
1944	auxin-type substances e.g., 2,4-D ∗	selective herbicides
1948	maleic hydrazide	inhibition of the growth of grass
1959	gibberellin	improvement in the quality of grapes
1959	chlormequat (Cycocel)	strengthening the stalks of cereals
1962	daminozide	improvement in the quality of apples and cherries
1966	cytokinins	improvement in the fructification of grapes
1971	ethephon (Ethrel)	increase in the latex flow in rubber trees
1973	glyphosine (Polaris)	increase in the sugar yield from cane
1979	mepiquat (Pix)	prevention of excessive growth of cotton
1987	inabenfide (Seritard)	strengthening the stalks of rice
1989	triapenthenol (Baronet)	improvement in the stability of rape

∗ 2,4-Dichlorophenoxyacetic acid.

Uses. Irrespective of whether a plant is wild or cultivated, its development normally falls short of its capacity, i.e., its genetically defined potential is not fully exploited. Limiting factors are temperature; shortage of light, water, and nutrients; competing plants; insect damage; and microorganisms.

Increased yields can be achieved in plant cultivation by measures such as adequate fertilization and irrigation, use of high-yield varieties, optimal soil treatment, and reduction of diseases, pests, and weeds with agricultural pesticides. Additional increases in plant production can also be obtained by using growth regulators. Some regulators only change the outer form of plants (morphoregulators). Substances that influence other properties of cultivated plants are also being increasingly investigated. These properties include plant constituents (sugar, protein), resistance to stress (dryness, heat, frost, salty soil), and rhythm of plant development (fruit set, induction of flowering, acceleration of maturity, and shedding of fruit and leaves, i.e., abscission).

The development of a marketable growth regulator generally takes longer than the development of other plant treatment agents; determination of the dose rate and the best time for application is often critical and requires extensive outdoor experimentation under varying conditions.

Growth regulators have to meet the same requirements for approval and control as other plant treatment agents (see → Fungicides, Agricultural, → Insect Control, → Weed Control). Detailed information about the product properties of the active agents (e. g., toxicity, formulation, solubility, application, and trade names) are given in [17], [18].

Growth regulators are usually applied in agriculture by spraying them on foliage. Although seed treatment has environmental advantages, this method is rarely implemented because application has to take place at a defined time before sowing. In horticulture, the agent is often added during watering and is taken up through the roots.

Economic Aspects [19]. Compared with the three main groups of plant protection agents (herbicides, insecticides, and fungicides), growth regulators have a relatively small share of the world market (ca. 4 %). The growth rate in sales is, however, comparatively high. At the end of the 1980s the entire market volume for growth regulators was ca. US $ 750×10^6 (end-user level). The defoliants and desiccants (agents for facilitating harvesting, especially of cotton, tobacco, and potatoes) alone accounted for about 40 % of sales and were predominantly agents with commodity status. The application of growth-retarding agents in European cereal and rape cultivation and in American cotton is another economically important sector.

The most important agents (see Table 1) are maleic hydrazide, chlormequat, ethephon, daminozide, gibberellic acid, glyphosine, mepiquat, and thidiazuron.

2. Classes of Growth Regulators

Growth regulators belong to so many different chemical families that classification according to their chemistry does not seem very useful. The classification system used here is based on mechanisms of action; many growth regulators exert effects that are similar or antagonistic to those of native phytohormones, allowing a rough qualitative classification [1, p. 10].

The names used for growth regulators, like those for other agents in pharmaceutics and plant protection, are numerous and confusing. Manufacturers not only use trade names, but also apply to national and international authorities (e.g., ISO) for a common name. The common name is normally an abbreviation of the chemical name and is used to denote the pure active agent.

2.1. Auxins and Auxin-Type Compounds

Auxins and auxin-type growth substances exert the typical effects of the natural phytohormone auxin (3-indolylacetic acid): the promotion of longitudinal growth by cell elongation, stimulation of cell division in the cambium and roots, and control of enzyme activity.

Auxins have not gained much practical importance as growth-stimulating agents because of their narrow therapeutic dose range. A small overdose can cause the growth-regulating effect to become a herbicidal effect. Auxin-type substances are much more important as herbicides than as growth regulators (→ Weed Control). The following auxins are of significance as growth regulators.

3-Indolylacetic acid [*87-51-4*], $C_{10}H_9NO_2$, M_r 175.2, was isolated from human urine by Kögl in 1934 [20].

Tryptophan is the starting material for the biosynthesis of this substance [15, p. 39]. It is used to stimulate root growth in cuttings, in the production of seedless fruit, and in the induction of flowering in pineapples. However, indolylacetic acid has been largely replaced by other carboxylic acids.

3-Indolylbutyric acid [*133-32-4*], IBA, $C_{12}H_{13}NO_2$, M_r 203.2, *mp* 123 – 125 °C, colorless crystals.

In the plant this acid is degraded to indolylacetic acid, presumably by β-oxidation. It is made from indole, γ-butyrolactone, and sodium hydroxide and is used in the same way as indolylacetic acid.
Trade names: Hormodin (MSD Agvet), Seradix (Rhône-Poulenc).

1-Naphthaleneacetic acid [*86-87-3*], $C_{12}H_{10}O_2$, M_r 186.2, *mp* 134 – 135 °C, colorless crystals, LD_{50} rat oral ≈ 2520 mg/kg.

This substance is produced by the hydrolysis of 1-naphthaleneacetonitrile, which is obtained by the chloromethylation of naphthalene and subsequent reaction with sodium cyanide. It is used for the same purposes as indolylacetic acid and to thin out apples, olives, oranges etc. and to inhibit germination of potatoes during storage.
Trade names: Celmone (Excel Ind.); Thin'n Stop-Drop (Platte Chem), Fruitone-N, NAA 800, Tree-Hold (Rhône-Poulenc); Olive Stop (UAP Special Products).

1-Naphthaleneacetamide [*86-86-2*], $C_{12}H_{10}NO$, M_r 185.2, *mp* 182 – 184 °C, LD_{50} rat oral ≈ 1000 mg/kg. It is used in the same way as naphthaleneacetic acid.
Trade names: Amid-Thin W, Rootone (Rhône-Poulenc, Greenwood Chemical).

2.2. Antiauxins

In a narrower sense, antiauxins are defined as substances that compete with auxins for specific

receptors [21]. Only agents that are antiauxins in a broader sense have achieved practical importance; they inhibit the transport of auxins in the plant and, thus, strongly affect growth and morphology [22]. Frequently, these effects are exploited in herbicides, as in the case of the morphactins derived from fluorene-9- carboxylic acid (→ Weed Control). The following antiauxins are used as growth regulators.

***N-m*-Tolylphthalamic acid** [*85-72-3*], N-m-t, $C_{15}H_{13}NO_3$, M_r 255.3, $LD_{50} \approx 5230$ mg/kg (oral, male albino rats).

This substance is used to improve the yield of tomatoes, beans, and cherries by increasing fructification.
Trade names: Tomaset, Duraset (Uniroyal, Makhteshim-Agan).

2.3. Gibberellins

Natural gibberellins (GA) have a wide spectrum of phytohormonal effects, especially in the regulation of growth by cell elongation and cell division and in the induction of hydrolytic enzymes. More than 70 natural gibberellins, each containing 19 or 20 carbon atoms, have been found [23]. The nomenclature of these substances (GA_1, GA_2 . . .) follows the order of their discovery. Not all the gibberellins are biologically active, some are precursors in the biogenesis of active (usually C_{19}) gibberellins and others are inactivated metabolites.

The biosynthesis of these diterpene compounds involves mevalonate as the starting product which is converted to geranylgeranyl pyrophosphate (→ Terpenes) [24]. The latter is cyclized to give the key substance *ent*-kaurene. Stepwise oxidation then yields the acid, which is converted to the GA_{12} aldehyde by subsequent oxidation and ring contraction. Further biosynthetic steps give the gibberellins, which all have a carboxyl group at position 10 of the skeleton.

Gibberellic acid [*77-06-5*], GA_3, $C_{19}H_{22}O_6$, M_r 346.4, *mp* 233 – 235 °C. This substance is produced biotechnologically from the fungus *Gibberella fujikuroi* (*Fusarium moniliforme*).

It is used in the United States at concentrations of 1 – 1000 ppm to produce seedless dessert grapes, to increase fruit and vegetable yields (celery and artichokes), and in the production of vegetable seeds.

Oral doses up to 1500 mg/kg produce no toxic symptoms in mice.
Trade names: Pro-Gibb, Pro Vide (Abbott Labs); Activol, Berelex, Grocel (ICI); Gibrel (MSD Agvet).

Promalin (Abbott), a mixture of GA_4/GA_7 with 6-benzyladenine, is also available for improving the quality and yield of apples.

2.4. Gibberellin Antagonists
